disease. Erythema nodosum remains the most common form of panniculitis, and although there is a long list of diseases and medications that have been associated, it is frequently not associated with an identifiable underlying condition. Some underlying conditions associated with erythema nodosum include inflammatory bowel disease; sarcoidosis; malignancies such as leukemia and lymphoma; infections (bacteria, *Yersinia*, rickettsiae, chlamydia, spirochetes, and protozoal disease); pregnancy; drugs (sulfonamides and contraceptives); and autoimmune diseases such as Behçet's disease, Sjögren's syndrome, reactive arthritis, and SLE.⁷⁴

As the understanding of lobular panniculitis has expanded, cases that were lumped into the wastebasket term of "Weber-Christian" disease are now recognized to be clearly definable and separate entities such as lupus panniculitis, cytophagic histiocytic panniculitis, α_1 -antitrypsin deficiency, factitial panniculitis, traumatic panniculitis, and calciphylaxis.⁷⁵⁻⁷⁷

Infections are recognized as a trigger of panniculitis, as exemplified by erythema nodosum due to streptococcal infection, hepatitis B or C associated with polyarteritis nodosa, infectious panniculitides often in immunocompromised hosts, and most recently some cases of erythema induratum/nodular vasculitis associated with *Mycobacterium tuberculosis*. In addition, atypical infections can themselves cause lesions that look like panniculitis.

An understanding of the heterogeneity of lymphomas that involve the fat is still evolving, but advances in differentiating various histologic and clinical outcomes are occurring.⁷⁸ Some patients thought to have lupus panniculitis on the basis of cytopenias and laboratory tests are actually diagnosed with subcutaneous lymphoma after careful review of their pathology.

Patients with panniculitis frequently have erythematous tender nodules, and the clinical presentation frequently is not specific enough to allow determination of the exact subtype of panniculitis without a biopsy. Patients with panniculitis can have associated symptoms such as low-grade fevers, fatigue, arthralgias, and myalgias.

An adequate skin biopsy, often involving an elliptical excision, is essential to properly diagnose the various entities that fall into the category of panniculitis (Table 43-1). Panniculitis is typically classified into four main subgroups: septal, lobular, mixed panniculitis, and panniculitis with vasculitis, and the exact nature of the cellular infiltrate also contributes to arriving at a proper diagnosis. There is no question that these overall categorizations help to narrow the differential in any given case, but at times there are overlapping features or reaction patterns that do not allow for a specific diagnosis. Clinical-pathologic correlation is important, as emphasized by a published review that has an expanded and useful classification of panniculitis.⁷⁹

There are anecdotes about the efficacy of combination antimalarials such as hydroxychloroquine and quinacrine in treating subcutaneous sarcoid, but no studies exist to allow definitive recommendations. Reports about the use of newer therapies such as mycophenolate mofetil and thalidomide for treatment of inflammatory causes of panniculitis such as nodular panniculitis and erythema nodosum are already in the literature and indicate that these drugs will likely evolve to be useful for these conditions.^{80,81}

Table 43-1 Classification of Panniculitis

I. Without prominent vasculitis
A. Septal inflammation
1. Lymphocytic and mixed: erythema nodosum and variants
2. Granulomatous: palisaded granulomatous diseases, sarcoidosis, subcutaneous infection: tuberculosis, syphilis
3. Sclerotic: scleroderma, eosinophilic fasciitis, lipodermatosclerosis, toxins
B. Lobular inflammation
1. Neutrophilic: infection, ruptured folliculitis and cysts, pancreatic fat necrosis
2. Lymphocytic: lupus panniculitis, poststeroid panniculitis, lymphoma/leukemia
3. Macrophagic: histiocytic cytophagic panniculitis
4. Granulomatous: erythema induratum/nodular vasculitis, palisaded granulomatous diseases, sarcoidosis, Crohn's disease
5. Mixed inflammation with many foam cells: α_1 -antitrypsin deficiency, Weber-Christian disease, traumatic fat necrosis
6. Eosinophilic: eosinophilic panniculitis, arthropod bites, parasites
7. Enzymatic fat necrosis: pancreatic enzyme panniculitis
8. Crystal deposits: sclerema neonatorum, subcutaneous fat necrosis of the newborn, gout, oxalosis
9. Embryonic fat pattern: lipoatrophy, lipodystrophy
II. With prominent vasculitis (septal or lobular)
A. Neutrophilic: leukocytoclastic vasculitis, subcutaneous polyarteritis nodosa, thrombophlebitis, ENL
B. Lymphocytic: nodular vasculitis, perniosis, angiocentric lymphomas
C. Granulomatous: nodular vasculitis/erythema induratum, ENL, granulomatosis with polyangiitis, Churg-Strauss allergic granulomatosis
III. Mixed patterns

ENL, erythema nodosum leprosum.

Efficacy of these and more established drugs such as NSAIDs, antimalarials, and methotrexate need to be studied, and outcomes will hopefully be more systematically evaluated.

RELAPSING POLYCHONDritis

The diagnosis of relapsing polychondritis (RP) is based on the typical clinical manifestations, with auricular findings seen in 90% of patients. Nasal and respiratory tract chondritis can occur, along with nonerosive inflammatory arthritis, cardiac valvular insufficiency, vasculitis, eye, and audiovestibular involvement. The estimated prevalence of 3.5 per million makes controlled trials nearly impossible. The etiology is unknown, but the pathogenesis appears to be mediated by an immune reaction to type II collagen. Clinical skin manifestations include inflammation of the ear, with sparing of the earlobe. Diagnosis includes the presence of a positive serum antibody test to type II collagen and a wedge biopsy that shows cartilage necrosis and perichondral inflammation with lymphocytes and histiocytes. Involvement of other cartilage areas including the upper airway should be assessed. Glucocorticoids are the therapeutic choice for reducing the inflammatory process in patients with RP. For patients with sustained disease, many immunosuppressive drugs have been used as steroid-sparing agents. There have been reports of response to tumor necrosis factor (TNF) inhibitors in patients otherwise refractory to therapy.⁸²

INFILTRATIVE DISEASES AND SKIN/ARTHRITIS

Amyloid

Type AL amyloidosis (primary amyloidosis) is rare, with an incidence of less than 1 per 100,000. Skin lesions may occur in up to 40% of these patients. Skin lesions can be an early sign of the disease and include purpura, petechiae, and ecchymoses due to infiltration of blood vessels by amyloid. Other skin findings include alopecia, plaques, and nodules, often found on flexor surfaces, the face, or the buccal mucosa. Bullae and nail dystrophy are occasionally seen. Diagnosis is confirmed by biopsy of lesional or nonlesional skin, along with urine and serum for immunoelectrophoresis to confirm the presence of a circulating monoclonal protein. Skin biopsy shows Congo-red positive, homogeneous, hyaline, fibrillary deposits. Treatment includes autologous stem cell transplantation, with approximately 50% of patients achieving prolonged remission with such therapy. Other effective therapies include the combination of melphalan with high-dose dexamethasone or the use of thalidomide.⁸³ The prognosis depends on the stage at the time of diagnosis, emphasizing the importance of recognizing the disease.

Sarcoidosis

Cutaneous involvement occurs in 20% to 25% of sarcoidosis cases and is most likely to be seen early in the disease. Cutaneous lesions can be classified as nonspecific, typically erythema nodosum, and specific or granulomatous. Erythema nodosum occurs frequently as part of Löfgren's syndrome, with bilateral hilar lymphadenopathy and acute iridocyclitis. This variant has a good prognosis and resolves in 80% within 2 years. The skin lesions of sarcoidosis generally have no prognostic significance or correlation with disease activity. Skin involvement has no effect on the course of the disease, and the number of skin lesions does not correlate with systemic disease. Skin plaques tend to be more persistent and commonly associated with chronic forms of the disease. Lupus pernio (Figure 43-15), with violaceous plaques on the nose, ears, cheeks, lips, and fingers, is often seen in long-standing sarcoidosis and is associated with upper airway involvement and pulmonary fibrosis.⁸⁴ Other forms of cutaneous sarcoidosis include papules, follicular papules, subcutaneous nodules, ulcerative lesions, alopecia, and ichthyosis. Cutaneous sarcoid can arise in scars. Because of the many types of presentation, diagnosis can be challenging and a skin biopsy is necessary to confirm the clinical suspicion. Mimickers of papules include xanthelasma, rosacea, trichoepithelioma, syphilis, LE, and granuloma annulare. Plaques can resemble lupus vulgaris, necrobiosis lipoidica, morphea, leprosy, *Leishmania*, or lupus erythematosus. Nodules can resemble lymphoma or other types of panniculitis. Treatment of cutaneous sarcoidosis depends on the degree of systemic involvement. Clearly patients who need prednisone for systemic disease often experience improvement of their cutaneous sarcoid. Patients with isolated skin disease or systemic disease not requiring aggressive therapy can benefit from topical or intralesional corticosteroids, topical tacrolimus,

Figure 43-15 Sarcoidosis with “apple-jelly” plaques on the face and lupus pernio, or nasal rim lesions.

hydroxychloroquine, combination antimalarials with hydroxychloroquine and quinacrine, or chloroquine. If antimalarials are not adequate, then methotrexate or oral retinoids may be used. There have been case reports, and small case series of successful therapy with thalidomide and TNF inhibitors, as well as laser remodeling of lupus pernio.^{85,86} There is some concern that interferon- α therapy may induce sarcoidosis.

MISCELLANEOUS SKIN DISEASES AND ARTHRITIS

Behçet's Disease

The criteria for Behçet's disease (BD) include recurrent oral and genital ulcers, eye lesions (uveitis or retinal vasculitis), characteristic skin lesions, and a positive pathergy test.⁸⁷ The pathergy test involves using a sterile needle to prick the forearm. The results are positive when the puncture causes an aseptic erythematous nodule or pustule that is more than 2 mm in diameter at 24 to 48 hours. A diagnosis is made if patients have recurrent oral ulceration plus at least two of the other findings without other clinical explanations. Skin lesions include erythema nodosum, pseudofolliculitis, or papulopustular lesions or acneiform nodules in postadolescents. Oral ulcers are painful and occur on the gingiva, tongue, and buccal and labial mucosa. Genital ulcers, usually larger and deeper than oral ulcers, are typically on the scrotum and penis in men and the vulva in women. Venous involvement including superficial thrombophlebitis and deep venous thrombosis can occur. On skin biopsy, small vessel vasculitis is common. Ulcer treatment includes topical corticosteroids, colchicine, and thalidomide. Systemic corticosteroids are prescribed for unresponsive erythema nodosum.

Familial Mediterranean Fever

Familial Mediterranean fever (FMF) is an autosomal recessive disease that tends to affect certain ethnic groups including Sephardic Jews, Arabs, Armenians, and Turks. There is a mutation on the short arm of chromosome 16, and the mutant protein pyrin likely plays an inhibitory role in the control of inflammation.^{88,89} It is characterized by recurrent, self-limited attacks of peritonitis, pleuritis, and synovitis. Erysipelas-like erythema (ELE) is the pathognomonic skin manifestation. This is characterized by tender erythematous, well-demarcated plaques, usually located on the lower legs.⁹⁰ They may be triggered by physical effort and subside spontaneously within 48 to 72 hours of bed rest. Fever and leukocytosis may accompany this condition. Other associated skin findings include Henoch-Schönlein purpura; non-specific purpura; erythema of the face, trunk, or palm; angioneurotic edema; Raynaud's phenomenon; pyoderma; and subcutaneous nodules. Secondary generalized amyloidosis may lead to chronic renal failure and death if not recognized. Skin biopsy shows edema of the superficial dermis and sparse perivascular infiltrate composed of a few lymphocytes, neutrophils, and nuclear dust, without vasculitis. Direct immunofluorescence shows deposits of C3 in the wall of small superficial vessels. Early treatment with colchicine, which prevents or diminishes the frequency and severity of the inflammatory episodes, can be beneficial.

Multicentric Reticulohistiocytosis

Multicentric reticulohistiocytosis (MRH) is a rare condition of unknown etiology that most frequently occurs in Caucasian women in their fifth and sixth decades. There is destructive symmetric arthritis, with arthritis mutilans developing in about 45% of cases, associated with cutaneous papulonodular lesions. Skin findings include cutaneous red-to-brown papules or nodules, typically on the face, dorsum of the fingers, and over the proximal and distal interphalangeal joints, but they can be in a more generalized distribution. A rarer presentation includes photodistributed erythema, often with targeting over joints that masquerades as DM.⁹¹ Diagnosis is made by skin biopsy, which shows infiltration of histiocytes and multinucleated giant cells. These changes can be seen in a variety of tissues including the heart, lungs, skeletal muscle, and gastrointestinal tract. The differential diagnosis of skin disease includes other infiltrative processes such as sarcoidosis and even leprosy. Treatment recommendations, based on mostly small case reports, include glucocorticoids and methotrexate, with use of cyclophosphamide and finally chlorambucil if the condition is unresponsive.⁹² Cyclosporine, TNF inhibitors, and bisphosphonates have also been used with reported benefit.⁹³ In about one-third of patients, MRH may precede or follow an underlying malignancy. Reported associated malignancies include breast, cervix, colon, stomach, lung, larynx, ovary, lymphoma, leukemia, sarcoma, melanoma, mesothelioma, and metastatic cancer of unknown primary.

Chronic Infantile Neurologic Cutaneous and Articular (CINCA) Syndrome

Mutations in cryopyrin (CIAS1, NALP3, PYPAF1), associated with increased proinflammatory cytokines, have been

found in about 50% of patients with CINCA syndrome.^{94,95} CINCA syndrome is characterized by a neonatal urticarial eruption, fever, arthritis, and leukocytosis. Other findings include chronic meningitis, papilledema, hearing loss, and growth retardation. Isolated reports suggest that TNF inhibitors, anakinra, and thalidomide can be beneficial therapeutically in these patients.

Acknowledgment

The authors want to acknowledge Dr. Nicole Rogers for her assistance with the figures. The work was supported by the Department of Veterans Affairs Veterans Health Administration, Office of Research Development, Biomedical Laboratory Research and Development and by the National Institutes of Health (NIH K24-AR 02207) to Victoria P. Werth.

The Eye and Rheumatic Diseases

JAMES T. ROSENBAUM

KEY POINTS

Symptoms of uveitis vary widely based on the location of the inflammation within the eye and the suddenness of onset.

Ankylosing spondylitis is the systemic disease most often associated with uveitis in North America and Europe.

During a lifetime, about 40% of patients with ankylosing spondylitis develop acute anterior uveitis.

The uveitis associated with HLA-B27 tends to be unilateral, recurrent, and sudden in onset. Recurrences sometimes affect the opposite eye.

Sarcoidosis frequently manifests as a uveitis.

Most patients with retinal vasculitis do not have a systemic vasculitis.

Many patients with scleritis have a systemic disease, such as rheumatoid arthritis.

Antineutrophilic cytoplasmic antibody testing helps to identify a subset of patients with severe scleritis.

Granulomatosis with polyangiitis (formerly Wegener's granulomatosis) is the rheumatic disease that most frequently involves the orbit.

Anterior ischemic optic neuropathy is the most common ocular manifestation of temporal arteritis.

Most patients with visual loss secondary to optic nerve ischemia do not have arteritis.

Virtually all of the systemic inflammatory diseases that require rheumatologic care tend to affect the eye or its surrounding structures. Table 44-1 presents the prototypic ocular manifestations of rheumatoid arthritis, systemic lupus erythematosus, Sjögren's syndrome, spondyloarthropathies, vasculitides including granulomatosis with polyangiitis (formerly Wegener's granulomatosis) and temporal arteritis, scleroderma, Behçet's syndrome, relapsing polychondritis, and dermatomyositis. Each of these diseases is addressed elsewhere in this text; this chapter focuses on specific ocular structures—the uvea, cornea, orbit, and optic nerve—and illustrates how inflammation of each might relate to an autoimmune or inflammatory process.

OCULAR ANATOMY AND PHYSIOLOGY

A diagram of the eye is shown in Figure 44-1. The eye is a tiny, but elegantly complex structure. The anterior segment of the eye includes the cornea, which is avascular and transparent when healthy. The lens also is an avascular

structure. The anterior chamber is filled with aqueous humor, which has homology to cerebrospinal fluid. When the blood-aqueous barrier is intact, the aqueous humor contains no leukocytes and very little protein. The blood-aqueous barrier, which resembles the blood-synovial barrier, is disrupted in anterior uveitis. In this case, a routine, noninvasive biomicroscopic or slit lamp examination would reveal leukocytes and increased protein in the anterior chamber. An ophthalmologist has the opportunity to observe two universal hallmarks of inflammation noninvasively.

The term *uvea* derives from the Latin word for “grape.” The anterior uvea includes the iris and the ciliary body. The aqueous humor is synthesized by the ciliary body. The posterior portion of the uvea is the choroid, which is a highly vascular tissue just posterior to the retina. Any portion of the uveal tract could become inflamed; adjacent tissue also is frequently inflamed. Anatomic subsets of uveitis include anterior uveitis, which consists of iritis or iridocyclitis (ciliary body inflammation); intermediate uveitis, in which leukocytes are present within the vitreous humor; and posterior uveitis, in which the choroid and the retina are inflamed. A *panuveitis* occurs when all portions of the uveal tract are inflamed. An attempt has been made to standardize the nomenclature used to describe uveitis by the Standardization of Uveitis Nomenclature Working Group,¹ although ambiguities persist because not all ophthalmologists follow these definitions as yet.

Signs and symptoms of uveitis depend on the portion of the uveal tract that is affected. An anterior uveitis, especially if it begins suddenly, is associated with redness, pain, and photophobia. Visual loss varies and often is due to macular edema if present (Figures 44-2 and 44-3). An intermediate uveitis usually causes floaters owing to leukocytes that enter the visual axis, although most floaters are due to aging or other changes within the vitreous humor. A posterior uveitis by itself does not usually produce pain or redness. Visual loss depends on the location and extent of the inflammatory process.

The outer tunic of the eye is known as the *sclera*. At the front of the eye, the sclera meets the cornea at a tissue known as the *limbus*. The most interior layer of the eye is an extension of the brain that responds to visual signals, the *retina*. The eye shares some common features with the joint, including the presence of hyaluronic acid primarily in the vitreous humor and the presence of type II collagen, although ocular inflammation is not a reported accompaniment of collagen-induced arthritis. Aggrecan is a proteoglycan present in both the eye and the joint. An autoimmune response to aggrecan in BALB/c mice can produce both arthritis and uveitis.²

Table 44-1 Most Characteristic Ocular Findings of Selected Rheumatic Diseases

Disease	Most Characteristic Eye Findings
Rheumatoid arthritis	Sicca Scleritis
Systemic lupus erythematosus	Sicca Cotton-wool spots
Sjögren's syndrome	Sicca
Spondyloarthritis	Acute anterior uveitis
Granulomatosis with polyangiitis	Scleritis Orbital inflammation
Temporal arteritis	Anterior ischemic optic neuropathy
Scleroderma	Sicca
Behçet's disease	Uveitis, retinal arteritis
Relapsing polychondritis	Scleritis, episcleritis, uveitis
Dermatomyositis	Heliotrope eyelids

OCULAR IMMUNE RESPONSE

The eye generally is regarded as an immune privileged site.³ From a teleologic perspective, many scientists believe that the eye has evolved mechanisms to avoid becoming inflamed because of the consequences this has for visual acuity. Similar to the brain, the internal portion of the eye has no lymphatics, although the conjunctiva on the ocular surface has lymphatic drainage. Portions of the eye—the cornea and the lens—are avascular. The aqueous humor contains several factors that are known to be immunosuppressive, including transforming growth factor- β and α -melanocyte-stimulating hormone. Several tissues within the eye express ligands that promote apoptosis, including tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) and Fas ligand. If a soluble antigen is injected into the anterior chamber, a cellular immune response is suppressed. This phenomenon is known as anterior chamber-associated immune deviation (ACAID). These factors are important to consider in the effort to understand why the eye sometimes is targeted as part of an immune or inflammatory disease.

UVEITIS

Rheumatologists may be consulted to identify a systemic disease in a patient with uveitis, and a rheumatologist often

**Figure 44-1** Diagram of the eye.**Figure 44-2** Fluorescein angiogram. The normal macula is avascular and does not stain with fluorescein dye. This patient has macular edema indicated by the donut-shaped pattern of dye in the center of the photo. The optic nerve is at the 3 o'clock position in the photo. Macular edema can complicate uveitis, even an anterior uveitis.

is asked to assist in the management of immunosuppression in selected patients with uveitis. In some referral practices for patients with uveitis, 40% of patients might have an associated systemic illness. Table 44-2 lists the differential diagnoses of uveitis. The immunologic diseases most likely to be associated with uveitis are listed in Table 44-3.

The most common systemic illness associated with uveitis in most North American practices is ankylosing spondylitis. From an epidemiologic perspective, anterior uveitis is more common than posterior or intermediate uveitis.⁴ About 50% of individuals who develop an anterior uveitis are HLA-B27 positive.⁵ The uveitis associated with HLA-B27 is almost always unilateral, is recurrent, is of relatively short duration (<3 months per attack), resolves completely between attacks, and is associated with reduced intraocular pressure (in contrast to herpes simplex, which can cause recurrent anterior uveitis associated with increased intraocular pressure).⁶ Hypopyon or pus in the anterior chamber sometimes is present in patients with HLA-B27-associated uveitis (Figure 44-4). Recurrent episodes can affect the contralateral eye, but simultaneous bilateral

**Figure 44-3** Optical coherence tomography produces precise imaging of the retinal structure. The ovoid black hole in the center of the image is due to macular edema, a major cause of visual loss in patients with uveitis.

Table 44-2 Differential Diagnosis of Uveitis

Infections—toxoplasmosis, syphilis, herpes simplex, herpes zoster, and cytomegalovirus
Systemic, immune-mediated diseases
Masquerade syndromes such as lymphoma
Syndromes confined to the eye, such as pars planitis, birdshot chorioretinopathy, and serpiginous choroiditis

involvement is rare. Many studies have tried to address the question of how frequently a patient with HLA-B27-associated anterior uveitis has an associated spondyloarthropathy. A wide range of answers have been suggested, and the percentage depends on the definition of spondyloarthropathy, but one reasonable estimate is that 80% of HLA-B27 positive patients with acute anterior, unilateral uveitis have associated spondyloarthropathy.⁵

The uveitis associated with reactive arthritis is indistinguishable from the uveitis associated with ankylosing spondylitis. In either of these entities, about 40% of patients develop acute anterior uveitis during a lifetime. Although conjunctivitis is part of the classic triad of reactive arthritis (in association with arthritis and nongonococcal urethritis), conjunctivitis is uncommon. A genome-wide screen for susceptibility genes for acute anterior uveitis identified loci that predispose to ankylosing spondylitis and loci that seem to be unassociated with susceptibility to ankylosing spondylitis.⁷

Approximately 5% of patients with inflammatory bowel disease and 7% of those with psoriatic arthritis develop uveitis. Although some of these patients have disease that is unilateral, anterior, and recurrent, many have disease that is bilateral, chronic in duration, and posterior to the lens.^{8,9} About half of all patients with Crohn's disease or psoriatic arthritis and uveitis are HLA-B27 positive.

Sarcoidosis is the second most common systemic disease associated with uveitis, at least in North America, and in some geographic areas it might be more common than spondyloarthritides. Sarcoidosis is promiscuous within the eye, meaning that it can affect a wide range of structures, including the orbit, lacrimal gland, anterior uvea, vitreous humor, choroid, retina, or optic nerve. Ocular inflammation with sarcoidosis frequently is termed *granulomatous* because large collections of cells deposit on the back of the cornea (Figure

**Figure 44-4** The creamy material at the bottom of the pupil is an accumulation of leukocytes, also known as a hypopyon.

44-5). A retinal vasculitis can be a prominent feature of sarcoidosis, even though systemic vasculitis is not a typical feature of the disease; this results in part from the manner in which vasculitis is diagnosed in the retina.

Histologic evidence of vessel wall destruction is rarely obtained because of the morbidity of a retinal biopsy. Instead, retinal vasculitis is diagnosed on the basis of perivascular sheathing along a vessel as seen on fundusoscopic examination (Figure 44-6), intraretinal hemorrhages that must be secondary to vascular injury, and fluorescein angiography indicating increased vascular permeability.¹⁰ The term *retinal vasculitis* is misleading to most rheumatologists because the classic systemic vasculitides, such as polyarteritis nodosa and granulomatosis with polyangiitis, rarely are associated with retinal vasculitis.

Sarcoidosis frequently manifests initially as an ocular problem.¹¹ An ocular symptom is the initial manifestation almost as frequently as a lung symptom. Sarcoidosis frequently involves the conjunctiva, which is an accessible tissue for biopsy confirmation of the diagnosis. In most series

**Figure 44-5** Keratic precipitates. The white dots result from concretions of cells depositing against the corneal endothelium. These keratic precipitates are large and usually are described as granulomatous even though a granuloma is not present histologically.

Figure 44-6 Retinal vasculitis. Arrows indicate areas of vascular sheathing or occlusion.

of patients with uveitis, about 30% of patients have uveitis that defies placement within a diagnostic category.¹² Many of these patients may have sarcoidosis that is difficult to find outside the eye. The sensitivity and specificity of studies such as a serum angiotensin-converting enzyme level or gallium scan for sarcoid that is primarily ocular are unknown. The author considers obtaining a chest computed tomography (CT) scan to look for symmetric hilar adenopathy in any patient who has a uveitis of unknown origin.¹³ The therapeutic implications of the result of the scan must be balanced against the cost and potential harm from radiation exposure.

Juvenile idiopathic arthritis comprises several different diseases. Patients with juvenile ankylosing spondylitis resemble their adult counterparts in that they can develop a sudden-onset, unilateral anterior uveitis. The subset of juvenile idiopathic arthritis that is most classically associated with uveitis tends to be female with onset of arthritis between 2 and 8 years old.¹⁴ The joint disease is pauciarticular, and most patients are antinuclear antibody positive. The uveitis tends to have an insidious onset such that pain and redness are almost always absent. The joint disease can be minimal as well, so that some patients are not diagnosed until a visual screening examination is performed when starting school. The eye disease usually is bilateral and very persistent, although remissions have been well described. Band keratopathy, which is the deposition of calcium superficially in the cornea, is a well-known and frequent complication of this form of uveitis (Figure 44-7). Patients also may develop glaucoma and posterior *synechiae*, a term that describes adhesions of the iris to the lens.

Other forms of uveitis associated with joint disease include Behçet's syndrome, relapsing polychondritis, and vasculitis such as Cogan's syndrome and Kawasaki's disease. In Behçet's syndrome, uveitis is often the symptom that "drives" the therapy, that is, it is often the manifestation that most requires systemic immunotherapy.¹⁵ Eye inflammation usually is bilateral and recurrent. In contrast to the recurrences typical of ankylosing spondylitis, recurrences of uveitis with Behçet's syndrome usually do not have complete resolution between attacks. A hallmark of Behçet's syndrome-associated uveitis is a retinal vasculitis. Retinal arteries are especially prone to be affected. The visual

prognosis with Behçet's syndrome can be grim, and blindness is a frequent concomitant of untreated ocular disease.

Relapsing polychondritis can have an impact on almost any portion of the eye, including the episclera, sclera, and uveal tract.¹⁶ Ocular inflammation is common.

Cogan's syndrome is classically defined as sensorineural hearing loss with corneal disease, especially an interstitial keratitis. This definition usually is broadened to include any ocular inflammatory process, such as uveitis or scleritis. Although uveitis can occur with polyarteritis or granulomatosis with polyangiitis, scleral disease is typical. In contrast, anterior uveitis in association with conjunctivitis is present in most patients with Kawasaki's disease.

Uveitis and arthritis occasionally can result from an infection such as Whipple's disease or Lyme disease. Uveal involvement with Lyme disease has been described but is extremely rare.

Some autoinflammatory diseases are associated with uveitis. Autoinflammatory diseases are characterized by widespread inflammation in the absence of detectable auto-antibodies. Many autoinflammatory syndromes respond dramatically to inhibition of interleukin-1. Blau's syndrome, which also is known as *familial granulomatous synovitis*, results from a single base change in the nucleotide-binding domain of the *CARD15* gene, which is also known as *NOD2* or *NLRC2*.¹⁷ Polymorphisms elsewhere in this same gene predispose to Crohn's disease. Blau's syndrome is characterized by childhood onset of uveitis, arthritis, and dermatitis. Inflammation in additional organ systems also has been described. The disease is autosomal dominant. The histopathology of affected skin or joint can show noncaseating granuloma as in sarcoidosis. Lung involvement has not been described in Blau's syndrome, however. Many patients thought to have so-called early-onset sarcoid have been shown by gene sequencing to have new mutations in the *NOD2* gene.¹⁸

Neonatal-onset multisystem inflammatory disease (NOMID), which also is known as *chronic infantile neurologic cutaneous articular syndrome* (CINCA), is an autosomal dominant autoinflammatory syndrome. Ocular involvement in NOMID is more variable than in Blau's syndrome. Characteristic findings include papilledema and uveitis.¹⁹

Figure 44-7 Band keratopathy is illustrated by calcific patches stretching across the cornea.

Treatment of uveitis depends on multiple factors, such as severity, location within the eye, patient preference, and the specific diagnosis (e.g., Behçet's syndrome might be especially responsive to infliximab²⁰ or interferon alfa²¹). For noninfectious causes of uveitis that involve the anterior portion of the eye, treatment usually begins with topical corticosteroids and often dilating drops to prevent posterior synechiae and to relieve spasm of the ciliary muscle. Periocular or intraocular corticosteroid injections, usually with triamcinolone, are given for inflammation posterior to the lens that is not responding to topical medication. Local corticosteroids can increase intraocular pressure, induce cataracts, interfere with the response to infection, and delay wound healing. A long-lasting corticosteroid implant containing fluocinolone has been approved by the Food and Drug Administration.²² All patients who elect this type of therapy develop a cataract if the lens has not already been surgically removed, and most patients develop glaucoma, many requiring surgery to control the intraocular pressure.

Systemic immunosuppressive therapy generally is reserved for patients with active, noninfectious causes of inflammation. For systemic immunosuppression to be indicated, usually the inflammation is bilateral and severe enough to interfere with activities of daily living. A variety of immunomodulatory medications have been tried to treat intraocular inflammation, including azathioprine, chlorambucil, cyclophosphamide, cyclosporine, daclizumab, infliximab, methotrexate, mycophenolate mofetil, and tacrolimus. The optimal choice depends on many factors, not the least of which is the empiric result of any therapeutic approach. Maintaining a treatment for uveitis usually requires some efficacy in association with good tolerability. In this regard, at least one study found methotrexate to be superior to other antimetabolites.²³ Because of the range of diseases being treated and the range of clinical response, there is room for all of these options in the therapeutic armamentarium of a uveitis clinic.

Biologic therapies are being used increasingly to treat patients with uveitis when the disease has proved refractory to other forms of immunomodulatory therapy. Infliximab is especially useful in the treatment of Behçet's disease.²⁰ One prospective study that assessed infliximab for a variety of forms of uveitis concluded that the drug was often effective, but that it was also surprisingly toxic.²⁴ Consequently, the role of biologic therapies in most specific forms of uveitis is inadequately studied.²⁵

SCLERITIS AND CORNEAL MELT

Scleritis often is divided into five categories: diffuse anterior, nodular, necrotizing, scleromalacia perforans, and posterior (Figure 44-8). Each of the first three categories results in a red, painful eye. Pain is more variable in scleromalacia perforans, in which a nodule pathologically similar to a rheumatoid nodule forms in the sclera (Figure 44-9). Pain also varies with posterior scleritis, and because the sclera extends back to the optic nerve, posterior scleritis can occur in a localized fashion such that the eye is not red. Because of the risk of perforation, the sclera is not normally biopsied, but biopsy studies have shown that scleritis is often a granulomatous inflammation of scleral tissue.²⁶

Figure 44-8 Scleral nodule. Active scleritis is present superior to the limbus. In this patient, scleritis has taken on a nodular configuration.

Patients with scleritis can develop complications within the eye, including uveitis, glaucoma, optic nerve edema, and retinal or choroidal distortion. A corneal melt or peripheral thinning of the cornea sometimes develops in individuals with severe scleritis and represents a potentially blinding complication of the disease (Figure 44-10).

About 50% of patients with scleritis have an associated systemic illness.²⁷ The most common of such illnesses are limited granulomatosis with polyangiitis and rheumatoid arthritis. Generally, the associated rheumatoid arthritis is long-standing and seropositive. Patients may have associated nodules, vasculitis, or pleuropericarditis. They have a shortened life expectancy compared with other patients with rheumatoid arthritis.²⁸ It is unusual for scleritis to be an initial manifestation of rheumatoid arthritis.

Granulomatosis with polyangiitis is commonly associated with scleritis. In contrast to rheumatoid arthritis, scleritis can be the initial manifestation of granulomatosis with polyangiitis, and our routine is to obtain antineutrophilic cytoplasmic antibody serology on any patient who presents with scleritis without an obvious systemic disease association. Other systemic associations with scleritis include

Figure 44-9 Scleromalacia has resulted in ulceration of the sclera and a bluish appearance.

Figure 44-10 Corneal melt. The white light of the slit lamp beam narrows over the peripheral cornea, where the tissue is thin.

inflammatory bowel disease, relapsing polychondritis, other vasculitides such as temporal arteritis, and ankylosing spondylitis. Infections are a rare but possible cause of scleritis. Tophaceous gout also has been reported as an unusual cause of scleritis.

Scleritis tends to be a painful and persistent disease that often lasts for years. In contrast, episcleritis involves more superficial tissue and is usually transient. Episcleritis may be a feature of rheumatoid arthritis, although many patients with episcleritis may not have any associated systemic illness. Complications within the eye, such as glaucoma or uveitis, are absent. Mild discomfort, rather than frank pain, is the usual presenting symptom. In contrast to scleritis, patients with episcleritis have vessels that constrict completely after 2.5% phenylephrine (Neo-Synephrine) is placed on the surface of the eye.

Some patients with scleritis, especially those who do not have an associated systemic illness, are treated adequately with an oral nonsteroidal anti-inflammatory drug. Some experts treat scleritis with locally injected corticosteroids, but this should be avoided if the sclera is thin (necrotizing disease). In addition, corticosteroid has the theoretical risk of promoting thinning. The usual option for patients who do not respond to nonsteroidal anti-inflammatory drugs is oral prednisone. Some patients can be maintained on low doses of prednisone, but many require the addition of an antimetabolite as a steroid-sparing drug. A substantial subset of patients with scleritis, especially patients who are positive for antineutrophilic cytoplasmic antibody, is best managed with an alkylating agent, such as cyclophosphamide. Because of the risk of this therapeutic approach, this drug is often given until the disease is in remission for several months; then therapy is switched to an antimetabolite to maintain the disease-free state.

ORBITAL DISEASE

Graves' disease, the most common orbital inflammatory disease, generally results in an orbital myositis that can be identified on imaging such as CT, ultrasound, or magnetic resonance imaging (MRI). From a rheumatologic perspective, granulomatosis with polyangiitis is the disease that

most commonly affects the orbit. The inflammation can be extremely painful and may result in blindness. Orbital inflammation sometimes is more recalcitrant to therapy than other aspects of granulomatosis with polyangiitis. A small series suggested that rituximab may be efficacious in patients with granulomatosis with polyangiitis, including those with orbital involvement.²⁹

Orbital pseudotumor, or nonspecific orbital inflammatory disease, is a diagnosis of exclusion that is made on the basis of objective orbital swelling as documented by imaging and a biopsy showing an inflammatory process that cannot be ascribed to another process such as Graves' disease. A biopsy specimen of the orbit is not always obtained, but it can be useful in ruling out lymphoma or a metastatic malignancy as the cause of the proptosis. Methotrexate is a therapeutic option to treat nonspecific orbital inflammation.³⁰ Other systemic diseases that commonly affect the orbit include sarcoidosis.

OPTIC NEURITIS

Optic nerve disease can result from many insults, including toxins (some of which are medications), vascular insufficiency as occurs from atherosclerotic disease or giant cell arteritis, and immunologic attack. The immune-mediated disease that most commonly affects the optic nerve is multiple sclerosis. This demyelinating condition generally starts suddenly in one eye with pain, an afferent pupillary defect, loss of color vision, and visual field loss typical of optic nerve disease. Initially, the optic nerve may show papilledema, or it may appear normal if the inflammation is retrobulbar. Over several weeks, the affected nerve usually becomes pale.

Demyelinating disease affecting the optic nerve generally is not treated by a rheumatologist, but a rare patient with optic nerve disease has inflammation that might require long-term immunosuppression. These patients carry a diagnosis labeled variously as autoimmune optic neuropathy or sometimes steroid-sensitive optic neuropathy. This diagnosis is clinically distinct from optic neuritis associated with multiple sclerosis in that MRI of the head should not indicate a demyelinating process, the disease is often bilateral, the kinetics of the inflammation is different from that of multiple sclerosis, and the disease usually responds to oral corticosteroids. In most centers, a neuro-ophthalmologist would be involved in establishing this diagnosis. Systemic lupus erythematosus and sarcoidosis may affect the optic nerve in this way, but many patients with this diagnosis do not have an associated systemic illness. Alkylating agent therapy or an antimetabolite can be beneficial for many patients with this entity.³¹

Sudden blindness is arguably the most feared consequence of temporal arteritis. This disease is characterized by granulomatous inflammation of multiple vessels above the waist. These frequently include the temporal artery and the posterior ciliary arteries. Inflammation in these latter vessels leads to anterior ischemic optic neuropathy (AION), which is ischemia of the optic nerve that manifests as sudden visual loss (Figure 44-11). Temporal arteritis also can affect the central retinal artery; this may result in blindness. In this condition, the funduscopy appearance of the eye shows markedly reduced arteriolar flow and a cherry-red spot in

Figure 44-11 Anterior ischemic optic neuropathy resulting from giant cell arteritis. The optic nerve is swollen, and surrounding hemorrhages are evident.

the macula. Temporal arteritis can cause diplopia by affecting circulation to extraocular muscles.

The visual loss associated with temporal arteritis is frequently labeled arteritic AION to distinguish it from the more common nonarteritic AION, which usually is attributable to small vessel atherosclerosis. Patients with arteritic AION typically are older than 50 years and have an erythrocyte sedimentation rate greater than 50 mm/hr. Many patients with arteritic AION have associated symptoms of polymyalgia rheumatica, jaw claudication, scalp tenderness, or temporal artery tenderness. The biopsy specimen of the temporal artery shows vasculitis in about 80% of patients with temporal arteritis if an adequate length of vessel is sampled. Twenty percent of patients with temporal arteritis might have a biopsy specimen of the artery that is negative because it has spared this vessel or has affected it in a sufficiently patchy distribution such that the biopsy specimen did not reveal the pathology. Patients with nonarteritic AION tend to have small optic nerve cups.

SUMMARY

In some ways, from a rheumatologist's perspective, the eye is a microcosm of the body. Its complex structures frequently reflect inflammation elsewhere. Treatment of many forms of ocular inflammation requires collaboration between a rheumatologist and an ophthalmologist.

Neck Pain

JOSEPH S. CHENG • MATTHEW J. MCGIRT •
CLINT DEVIN

KEY POINTS

Neck pain is a ubiquitous condition associated with enormous medical and legal costs in the United States.

Physicians need to differentiate causes of neck pain that can be managed conservatively from causes that require more aggressive treatments.

Knowledge of the anatomy helps diagnosis and the differentiation of symptoms from a musculoskeletal, neurogenic, or vascular etiology.

The history and clinical examination help focus the differential diagnosis and help to identify the origin of the neck pain based on the anatomy and physiology.

Indicated imaging studies, neurophysiologic procedures, and laboratory studies aid in diagnosis and determining a treatment plan for the patient's symptoms.

In the absence of spinal instability, neurologic deficit, infectious process, or neoplastic process, the patient may benefit from conservative treatment with expectant recovery in time.

EPIDEMIOLOGY

Pain is an evolutionary protective mechanism to prevent further tissue damage. Neck pain is a ubiquitous condition with a lifetime prevalence of 67% to 71%.¹ The point prevalence of neck pain ranges between 10% and 15%, with total annual costs for neck and low back pain corresponding to 1% of the gross national product (GNP) in Sweden, and direct health service costs representing only a small fraction of this percentage.²⁻⁴ The medical and legal expenses associated with neck pain can be enormous, as in whiplash injuries, which alone can cost \$29 billion annually in the United States.⁵

Neck pain may originate from various anatomic sources, including paraspinal soft tissues, intervertebral joints and disks, compression of the spinal cord or nerve roots, and referred visceral pain (Figure 45-1). The origin of neck pain has a wide differential diagnosis, which can include

trauma, degenerative changes, infection, and autoimmune disorders such as rheumatoid arthritis and ankylosing spondylitis.

The perception and resultant reporting of this pain vary significantly according to cultural and social circumstances. Honeyman and Jacobs noted that Australian Aborigines significantly underreport pain and are rarely disabled by pain.⁶ Social circumstances also play an important role in an individual's ability to cope with and overcome neck pain. Studies have demonstrated worse outcomes following discectomy for patients with a workers' compensation claim or litigation surrounding their condition.⁷ These studies indicate nonorganic contributions to neck pain for secondary gain. Fortunately, most episodes of acute neck pain resolve with "tincture of time" and patient education.

Physicians need to be able to differentiate causes of neck pain that can be managed with a conservative approach from those that require more aggressive treatment. An understanding of anatomy and physiology and of their association with the pathogenesis of neck pain provides the basis for obtaining a thorough history, physical examination findings, and ancillary data with the ultimate goal of effective treatment.

ANATOMY

The cervical spine consists of seven vertebrae (C1 through C7). The bony anatomy of the atlas (C1) and axis (C2) is unique, whereas C3-C7 demonstrates fairly consistent anatomy (Figure 45-2). The atlas has no vertebral body, and its lateral masses articulate with the occipital condyles of the skull, forming the atlanto-occipital joints supported by anterior and posterior occipital membranes.⁸ The atlanto-occipital joint is responsible for approximately 50% of total flexion and extension in the neck, and functional implications are clear when this motion is lost. The axis (C2) has the dens or an odontoid peg that projects upward and anterior to articulate with the posterior aspect of the anterior arch of the atlas. The principal stabilizer of the odontoid to the anterior arch of the atlas is the transverse ligament; alar and apical ligaments act as secondary stabilizers. This true synovial joint is susceptible to inflammatory processes such as those seen with rheumatoid arthritis. No intervertebral

disk is present between the atlanto-occipital joint and the atlantoaxial joint, and without conferred stability from a disk, destructive inflammatory arthritides may result in instability.⁹ The atlantoaxial articulation provides approximately 50% of rotatory motion of the cervical spine.

The subaxial cervical spine consists of C3 through C7 vertebrae, all demonstrating fairly similar anatomy. Each vertebra consists of a body, two interconnecting pedicles, two lateral masses, two transverse processes, two laminae, and spinous processes. Transverse and spinous processes

Figure 45-2 Cervical spine anatomy. **A**, Cervical spine. Anterior view of articulated cervical vertebrae. **B**, Posterior view of the skull, seven cervical vertebrae, and first thoracic vertebra.

project outward, providing attachment for ligaments and muscles, and creating a moment arm to facilitate motion. The spinous processes of C3 through C6 are bifid, whereas the C7 spinous process usually is not. However, the C7 spinous process is large and is the next most prominent and most easily palpable spinous process below C2.

Five articulations are present between vertebrae from C2 through C7, including the intervertebral disk, two uncovertebral joints, and two facet (zygoapophyseal) joints. Facet joints are true apophyseal joints with hyaline cartilage articulations, intervening menisci, synovial lining, and a joint capsule. This composition makes them susceptible to degenerative changes and systemic arthritides. The cartilage and the synovial lining are aneural, whereas the joint capsule is highly innervated by the dorsal primary ramus. The facet joints are angled approximately 45 degrees from the transverse plane, articulating in concert with the uncovertebral joints and ligaments.

Intervertebral disks increase in size from C2 downward, giving the cervical spine its characteristic lordotic shape. Each disk consists of an outer annulus fibrosus and an inner nucleus pulposus, as well as cephalad and caudad end plates. The annulus fibrosus consists of type I collagen, which helps give form to the disk and provides tensile strength. The annulus fibrosus is innervated by the sinuvertebral nerve, formed by branches of the ventral nerve root and the sympathetic plexus.¹⁰ The nucleus pulposus consists of type II collagen and proteoglycans, which interact with water to resist compressive stress. Pressure within the disk is greatest with flexion, which may explain why those with a disk herniation find this position most uncomfortable.¹¹ Disk degeneration with aging includes loss of water content and resultant loss of height, annular tears, and myxomatous changes, increasing the risk of disk herniation. This typically occurs in the posterolateral aspect of the disk, where the posterior longitudinal ligament is not present and annulus fibrosus is at its weakest, medial to the uncovertebral joints.

The spinal column is supported by the interplay of ligaments and muscles (Figure 45-3). The anterior longitudinal ligament (ALL) and the posterior longitudinal ligament (PLL) course along the anterior and posterior aspects of the vertebral bodies; the anterior longitudinal ligament resists hyperextension, and the posterior longitudinal ligament resists hyperflexion. The ligamentum flavum joins the laminae of adjacent vertebrae and may become thickened, creating stenosis in the spinal canal. In a similar manner, the interspinous ligament joins the spinous process of adjacent vertebrae. The supraspinous ligament originates as the nuchal ligament at the occiput and extends caudally as an aponeurosis until it is attached to the tip of the spinous processes of C7; it then continues to the lumbar region. Fourteen paired anterior, lateral, and posterior muscles help to orchestrate complex movements of the neck.

A brief review of the spinal cord and nerve roots is beneficial for a thorough evaluation. Grossly, the spinal cord is divided into the posterior column, the lateral column, and the anterior column. The posterior column mediates proprioceptive, vibratory, and tactile sensation; the lateral column is a conduit for motor fibers, along with pain and temperature sensation from the contralateral side of the body; the anterior column conveys crude touch sensation.

Figure 45-3 Cervical spine anatomy. Sagittal view of the lower head and neck shows the relationship of the spinal cord and brain stem to the bones, ligaments, and joints between bodies of the cervical vertebrae. Cervical lordosis can be seen, as can the relationship of the anterior and posterior longitudinal ligaments to intervertebral disks and ligaments at the craniocervical junction.

Eight total cervical nerve roots are present as the dorsal and ventral roots converge to form the spinal nerve within the vertebral foramen. Cervical nerve roots enter the intervertebral foramina by passing over the top of the corresponding pedicle, except the C8 cervical nerve, which lies between C7 and T1. Therefore, C5-C6 posterolateral disk herniation will affect the C6 nerve root. The nerve root occupies approximately one-third of the foramen (Figure 45-4). Space available for the nerve root is decreased with neck extension and degenerative changes, and is increased with neck flexion.

The anterior spinal artery arises from the vertebral arteries and supplies most of the spinal cord, excluding the posterior columns. The posterior columns receive their blood supply from the two posterior spinal arteries, which originate from the inferior cerebellar artery or the vertebral arteries. The vertebral arteries arise from the subclavian arteries and course through the C6 transverse foramen cephalad, passing anterior to the emerging cervical nerve root at each level. They pass behind the lateral mass of C1 and enter the foramen magnum, where they rejoin to form the basilar artery. Diseases such as dissection of the vessel can be associated with severe neck pain, and impairment of blood flow through the vertebral artery can result in posterior circulation signs such as nystagmus, vertigo, drop attacks, dysarthria, and visual impairment. These symptoms

Figure 45-4 Cervical spine neural elements. Localized cervical pain is mediated primarily through the posterior primary ramus and the recurrent meningeal (sinuvertebral) nerves, which supply structures within the spinal canal. The recurrent meningeal nerves arise from rami communicantes and enter the spinal canal via intervertebral foramina; branches ascend and descend one or more levels, interconnecting with recurrent meningeal nerves from other levels, and innervating, among other structures, the anterior and posterior longitudinal ligaments, the anterior and posterior portions of the dura, and blood vessels. (From Levin KH, editor: Neck and back pain: continuum 7 (no. 1), Philadelphia, 2002, Lippincott Williams & Wilkins, p 9.)

are often associated with head position, and a critical reduction in blood flow can result in a cerebellar infarction.

The cervical spine is the most mobile segment of the spine; an approximate 90-degree arc of motion occurs in flexion and extension, three-quarters of which is due to extension (Table 45-1). The maximal range of motion in the sagittal plane within the subaxial spine is seen at the C5-C6 level, making this a common site of disk degeneration. Rotation encompasses approximately 80 to 90 degrees of motion, and 50% of this occurs at the atlantoaxial joint. As is seen with extension, rotation reduces the cross-sectional area of the spinal canal. The cervical spine demonstrates 30 degrees of lateral mobility in each direction; this typically occurs with some degree of rotation secondary to the orientation of the facet joints.

AXIAL NECK PAIN

Axial neck pain may originate from any tissue that receives innervation, including zygoapophyseal joints, cervical disks, vertebral periosteum, posterior neck muscles, cervical dura mater, occipito-atlantoaxial joints, and vertebral arteries. Sources may include degenerative, traumatic, malignant, infectious, or systemic inflammatory processes. Zygoapophyseal joints and cervical disks have the greatest quantity of direct supporting data suggesting these sites as the origin of

axial neck pain. Provocative injection into the facet joint in asymptomatic volunteers invokes a reproducible pattern of occipital or axial neck pain.¹² This pattern of pain can be accurately diagnosed and treated for at least a short time with anesthetic injections targeted at the joint capsule itself, or with blockage of the respective dorsal primary ramus.¹³⁻¹⁵ Degenerative arthritis within the upper cervical spine can manifest as suboccipital headaches denoted as *cervicogenic headaches*, which are thought to result from irritation of the greater occipital nerve. Typically, arthritis within the atlanto-occipital joints is made worse by provocative neck flexion and extension, whereas atlantoaxial arthritis is made worse by rotation. This is supported by investigators who injected asymptomatic volunteers at the atlanto-occipital and atlantoaxial joints, reproducing this pattern of pain.¹⁶ Relief of suboccipital pain may be attained with fluoroscopically guided injection of corticosteroid into the diseased joint, or fusion of these joints in recalcitrant cases.

The cervical disk is a controversial source of axial neck pain, which occurs as the result of insult to the highly innervated annulus fibrosus. This idea is based on provocative diskography, whereby a diseased disk is fluoroscopically injected to a given pressure, and pain is reproduced in reliable patterns. In a true-positive or *concordant study*, an adjacent normal disk should not produce pain when injected. Using this method, several studies have implicated cervical disks as the source of axial neck pain.¹⁷⁻¹⁹ Even with careful technique, a false-positive result can occur, and it is not unusual to have a *nonconcordant study* in which multiple disks elicit a pain response despite being normal.¹⁷ Interventions directed at treating the disk for isolated axial neck pain have been found to be unpredictable, although the cervical disk is likely to contribute to axial neck pain.

Myofascial pain due to irritation of the muscles about the neck can contribute to axial neck pain. Patients with

Table 45-1 Age and Normal Cervical Movement

Age (yr)	Flexion-Extension (degrees)	Lateral Rotation (degrees)	Lateral Flexion (degrees)
<30	90	90	45
31-50	70	90	45
>50	60	90	30

chronic myofascial pain have been shown to have a lower level of high-energy phosphates in involved muscle tissue.²⁰ Myofascial pain can be the original source of neck pain or, more commonly, a manifestation of postural adaptations and compensatory overuse of normal tissue that remains after the injured structure heals. A more generalized form of this is fibromyalgia, a widespread disorder defined by diffuse pain affecting all four quadrants of the body, with at least 11 of 18 pressure points noted as positive. Patients have associated symptoms of fatigue, cognitive difficulties, and irritable bowel syndrome, and a nondermatomal pattern of dysesthesias, weakness, and paresthesias.²¹

Systemic inflammatory arthropathies causing neck pain typically demonstrate the classic pattern of morning stiffness, polyarticular involvement, rigidity, and associated cutaneous manifestations. Rheumatoid arthritis (RA) often involves the cervical spine, initially causing stiffness and later causing pain, potentially leading to instability. After the hands and feet, the cervical spine is the most common site of disease involvement in RA.²² The upper cervical spine is most commonly involved (occiput to C2), followed by the subaxial cervical spine (C3-C7). The likelihood of developing cervical spine pathology can be predicted by the extent of rheumatoid changes that occur in the hands and feet. Basilar invagination is one such manifestation, whereby C1 lateral masses erode, allowing the odontoid peg to settle into the foramen magnum, placing pressure on the brain stem with potential for instantaneous death. The atlanto-axial joint can demonstrate instability with potential for neurologic injury. Because of these potentially catastrophic complications, dynamic radiographs of the cervical spine should be obtained before any procedure requiring intubation is performed. Seronegative spondyloarthropathies that can manifest with neck pain include ankylosing spondylitis, psoriatic arthritis, and reactive arthritis. In 70% of patients, psoriatic arthritis will manifest with skin lesions before arthritis develops; reactive arthritis rarely involves the cervical spine.

Ankylosing spondylitis often affects the entire axial skeleton and is seen as limited lumbar motion and chest expansion with later involvement of the cervical spine. In progressive patterns, the cervical spine takes on a kyphotic deformity. As the spine fuses, it biomechanically becomes similar to a long bone; minor trauma with neck pain should be taken very seriously in these patients. Even in the face of negative plain radiographs, patients should be worked up extensively with strict spine precautions and with neutral alignment varying with the baseline spinal curvature; frequent neurologic evaluations should be performed to check for development of an epidural hematoma.

Infection and neoplasms can cause axial neck pain through bone destruction with irritation of vertebral body periosteal nerves and altered biomechanics of the facet joints and cervical disks. The onus is upon the clinician to identify these patients at the initial visit because a delay in diagnosis can have catastrophic consequences. Red flags for axial neck pain that require further workup at the initial presentation include elderly patients, patients with a history of malignancy, immunocompromised patients, and those with fever, chills, unexplained weight loss, fatigue, nighttime awakening, recent antecedent bacteremia, and severe nonmechanical neck pain.²¹

Patients who have undergone previous cervical spine surgery should be evaluated for the presence of pseudoarthrosis or iatrogenic instability. *Pseudoarthrosis* is failure of an attempted arthrodesis or fracture to fully heal with bridging bone. Patients will describe a “honeymoon” period, whereby they did well for 3 to 6 months following surgery. Patients then develop worsening axial neck and interscapular pain with associated headaches. This can be diagnosed on plain radiographs with evidence of hardware loosening or movement on dynamic images. Computed tomography (CT) scanning with coronal and sagittal reconstructions should be done to more definitively diagnose a pseudoarthrosis. Once pseudoarthrosis has been diagnosed, a surgical consult should be obtained, the patient should be counseled on smoking cessation given the deleterious effects of nicotine and carbon monoxide on bone healing, and a bone metabolic workup should be undertaken. An additional cause of neck pain following surgery is iatrogenic instability, whereby the surgery itself creates pathologic motion. This requires a surgical consultation to determine whether stabilization is warranted.

RADICULOPATHY AND MYELOPATHY

The clinician must determine whether there is evidence of nerve root compression, termed *radiculopathy*, versus spinal cord compression, termed *myelopathy*. Cervical spondylosis with changes within the disk may cause loss of height with posterior bulging of the disk into the spinal canal and foramen. As the disk collapses, the posterior soft tissue structures, including the ligamentum flavum and the facet joint capsule, fold inward, further compromising the spinal canal and neural foramen. Pressure that once was dispersed throughout the disk is transferred to the facet joints and uncinat processes, resulting in the development of bone overgrowth or osteophytes and causing extrinsic pressure on the nerve root or spinal cord.

In radiculopathy, mechanical distortion of the nerve leads to increased vascular permeability, resulting in chronic edema and eventually fibrosis. This causes hypersensitivity of the nerve root with an inflammatory response mediated by chemicals released from the cell bodies of sensory neurons and cervical disks.²³ Compression of the dorsal root ganglion is felt to be especially important in producing radicular pain.²⁴ Clinically, this presents with pain in a dermatomal distribution; dermatomes for the higher cervical nerve roots, including C3 and C4, are found along the posterior scapula, and the pain should not be confused with isolated axial neck pain.²⁵ Minor symptoms that are tolerable may be treated with conservative care, but persistent compression on a nerve root can lead to sensory loss and weakness. Disabling deficits should be treated operatively given that prolonged nerve compression can result in irreversible changes. In patients without a neurologic deficit, it is reasonable to expect a good outcome with conservative care.²⁶

Myelopathy has a clinical presentation of long tract signs resulting from compression of the spinal cord. Factors that contribute to the development of myelopathy include a congenitally narrow spinal canal, dynamic cord compression, dynamic thickening of the spinal cord, and vascular changes. The anterior-posterior diameter in the subaxial spine for a normal adult measures 17 to 18 mm. The cord

measures 10 mm, and diameters less than 13 mm are considered to be congenitally stenotic. The shape of the spinal cord deformity has a strong association with the development of myelopathy; patients with a banana-shaped cord on axial views had evidence of myelopathy 98% of the time.²⁷ Ono and associates described a ratio whereby the anterior-posterior diameter of the spinal cord is divided by the transverse diameter of the cord. Patients with a ratio of less than 0.40 tended to have severe neurologic deficits.²⁸ Patients may have dynamic cord compression with signs and symptoms of myelopathy only during neck flexion and extension. The space available for the cord is decreased during neck extension owing to infolding of the ligamentum flavum and overlapping of the lamina. In addition, the spinal cord shortens during neck extension, effectively increasing the diameter and making it more prone to compression by posterior structures. In flexion, the cord lengthens and drapes over anterior degenerated disks and osteophytes.²⁹

Myelopathy can be exacerbated by altered biomechanics from degenerated segments, as when a given level stiffens, the level above can become hypermobile.³⁰ A certain subset of patients can develop myelopathy in the absence of mechanical compression; this has been attributed to ischemic insult.³¹ It has been shown in a canine model that in the setting of spinal cord compression, additive ischemia results in significantly worse outcomes, because over time the spinal cord demonstrates permanent irreversible changes.³² Patients with mild cases of myelopathy that does not affect activities of daily living can be closely followed.³³ Those with more severe deficits or progressive deficits tend to deteriorate over time with conservative care, and it is recommended these patients should undergo surgery to decompress the spinal cord.³⁴

CLINICAL FEATURES

In terms of functional anatomic pathways, neck pain is mediated via somatic or autonomic pathways.³⁵ Somatic pain is the most common, being perceived in dermatomes, myotomes, or sclerotomes. Pain originating in the autonomic pathway, or in the sympathetic nervous system, may fall into somatic segmental distributions, vascular supply distributions, peripheral nerve distributions, or nonconforming patterns. Because pain mediation pathways may have significant overlap, additional clinical information regarding characteristics of neck pain, along with diagnostic studies, complements the determination of pain origin when localization based on functional anatomy is not sufficient.

Patient History

Neck pain is the most common symptom of cervical spine pathology; correctly characterizing it helps to identify conditions requiring immediate treatment. Important characteristics to note include onset, distribution, frequency, duration, quality, and aggravating factors, as well as the presence of neurologic symptoms other than pain. In general, pain that is present only intermittently may be indicative of instability or motion, whereas constant and increasing pain evokes concern regarding a mass effect. New-onset and relatively short duration generalized neck

pain is likely related to benign pathology such as muscle strain, whereas a longer duration of symptoms indicates significant or progressive pathology. Well-localized pain indicates specific nerve root irritation, whereas poorly defined pain may derive from irritation of deep connective tissue structures such as muscle, joint, bone, or disk. Aggravating and relieving factors may help elucidate biomechanical changes in the cervical spine that are contributing to the symptoms.

Localized axial neck pain is commonly reported as originating posteriorly with extension into the shoulder or occiput. Localized pain of myofascial origin may worsen with neck flexion, whereas diskogenic neck pain will worsen with neck extension or rotation. Pain referred to the occiput usually indicates pathologic changes in the upper cervical spine and may radiate down the neck and to the ear. Shoulder girdle pain develops secondary to postural adaptations from initial neck pain symptoms. It is not uncommon for pain to be referred from the shoulder, heart, lungs, viscera, or temporomandibular joint to the neck region as the result of overlapping nerve distribution. Symptoms may arise owing to irritation or activation of receptors directly, as is seen in articular pain, pseudoarticular pain, vascular and cervicogenic headaches, pseudo-angina pectoris, eye and ear symptoms, and throat symptoms.

Articular symptoms arise from innervation to the facet and uncovertebral joints causing local pain and stiffness. Patients often state that their symptoms are made worse with inactivity and describe feelings of clicking, grating, or “sand” in the neck. Pseudoarticular pain may be felt in the shoulder and elbow, with true pathology originating from the neck. Vascular symptoms result from compression of the vertebral artery by osteophytes or a protruding disk. Symptoms may intensify with neck movement or with certain postures. Tenosynovitis and tendinitis may involve the rotator cuff and tendons about the elbow, wrist, or hand. Stenosis or fibrosis of tendon sheaths or palmar fascia may be present, along with trigger points over the affected joints, giving a false impression of local pathology.³⁶

Localization of Pain Generators

Pain may be somatic or autonomic and is not always felt in precise anatomic zones. Overlapping sensory supplies may be present, as well as radiation in spinal segments by recruitment within the spinal column, causing difficulty in localization. Somatic pain is caused by cervical nerve root irritation. It is the most common type of pain, and diabetic patients are more susceptible to this nerve root irritation. Neurologic deficits correspond with the offending disk level in 80% of patients.³⁷ Neuralgic and myalgic pain describes symptoms related to compression of different areas of the nerve root. Neuralgic pain originates from irritation of the dorsal sensory root and has a “lightning” or “electric” sensation, which tends to be dermatomal and associated with numbness and paresthesia. Pain tends to present more proximally and paresthesia more distally. Myalgic pain occurs with irritation of the ventral motor root. This pain is described as a deep, boring, unpleasant sensation that tends to be poorly localized because of its referral to sclerotomal areas. These sensations conform to the areas of muscles present that are innervated by the compressed nerve root.

Table 45-2 Cervical Nerve Root Segments and Corresponding Clinical Signs and Symptoms

Nerve Root	Symptom	Correlate
C3 C4	Suboccipital pain with extension to the back of the ear Pain from caudad aspect of the neck to superior aspect of the shoulder	If C3, C4, and C5 are all involved, may cause paradoxical breathing
C5	Numbness over shoulder and down lateral aspect of arm to midportion. Deltoid muscle may be weak, and biceps reflex, which is innervated by C5-C6, may be affected.	
C6	Radiating pain and numbness down the lateral aspect of arm and forearm to the thumb and IF ("six shooter"). Weakness in wrist extension, elbow flexion, and supination. Diminished brachioradialis and biceps reflex.	Sensory component can mimic carpal tunnel syndrome
C7	Numbness and pain down the posterior aspect of arm and forearm to LF. Weakness in the triceps, wrist flexion, and finger extensors.	Most frequent. Entrapment of posterior interosseous nerve can mimic motor component; however, no sensory deficits are present.
C8 T1	Pain and numbness down the medial aspect of arm and forearm into the small ring finger. Weakness in the FDP to IF and LF and FPL.	AIN entrapment can mimic motor component of C8 or T1; however, sensory changes and involvement of thenar muscles will not be present. Ulnar nerve entrapment will spare short thenar muscles with exception of ADP. Does not involve FPL or FDP to IF and LF.

ADP, adductor pollicis; AIN, anterior interosseous nerve; FDP, flexor digitorum profundus; FPL, flexor pollicis longus; IF, index finger; LF, long finger..

Autonomically mediated symptoms result in dizziness, blurring of vision, tinnitus, retro-ocular pain, and facial and jaw pain.

It is important to determine whether axial neck pain is isolated, or if radiating pain, weakness, changes in sensation, or alterations in proprioception are associated. Compression of a nerve root often can be localized by identifying the distribution of pain, paresthesias, or weakness as they follow the segmental distribution of that respective nerve root (Table 45-2). Sensory loss may be characterized by the patient in precise terms with a description of numbness, or alternatively may consist of vague symptoms of swelling or boggiess to the skin. If the face, head, or tongue is involved, the upper three nerve roots of the cervical plexus may be affected. Numbness of the neck, shoulder, arm, forearm, or fingers indicates involvement of C5-T1. Weakness, as occurs with sensory changes, appears in a graded fashion, depending on the amount of compression upon the nerve root. This event will present clinically with an obvious functional deficit or more subtle findings, made obvious only by repetitive testing. The clinician must be attuned to these subtle complaints of weakness, which may be described by the patient as a feeling of heaviness of the limbs, early fatigue, or insufficient power grip. If obvious atrophy is present in a muscle, more than one nerve root is affected as a result of the evolutionary benefit of multiple levels of innervation for a given muscle. Alterations in proprioception are due to compression of the dorsal column of the spinal cord. This will be described by the patient as symptoms of clumsiness, with complaints of tripping or dropping objects. This is a matter of concern for the more ominous condition of myelopathy, which may occur secondary to spinal cord compression.

Cervical spinal disease classically causes isolated axial neck pain or radicular pain that radiates to the shoulder or down the upper extremity (Table 45-3). However, less commonly, it can be the cause of headache, pseudo-angina pectoris, and otolaryngologic sensations. Cervicogenic occipital headaches can be compounded by adaptive changes in the posterior occipital muscles, often spreading

to the eye region and manifesting as dull rather than pulsating pain. These headaches are unique in that they are aggravated by neck movements. Patients typically have migraine-like symptoms such as phonophobia or photophobia.

Pseudo-angina pectoris has been reported as the result of cervical spinal disease and may be confused with angina pectoris or breast pain in women (Figure 45-5). In the presence of a C6-C7 lesion, neuralgic or myalgic pain may be noted, along with tenderness in the precordium or scapular region. Heart disease is differentiated from symptoms associated with C6-C7 dysfunction on the basis of muscle weakness, fasciculations, or sensory or reflex changes. Differentiation of these two pathologies may be difficult when true angina and pseudoangina coexist in the same patient.³⁸

Cervical spinal disease may manifest in the form of eye, ear, and throat symptoms (see Figure 45-5). Eye and ear symptoms may arise from irritation of the plexuses surrounding the vertebral and internal carotid arteries. Eye symptoms can present as blurring of vision relieved by changing neck position, increased tearing, orbital and retro-orbital pain, or descriptions of eyes being "pulled backward" or "pushed forward." Altered equilibrium with associated gait disturbances may result from irritation of the surrounding sympathetic plexus or from vertebral insufficiency. Hearing can be affected, with tinnitus and altered auditory acuity

Table 45-3 Cervical Pain Referral Pathways

Location of Pain	Source
Upper posterolateral cervical region	C0-C1, C1-C2, C2-C3
Occipital region	C2-C3, C3
Upper posterior cervical region	C2-C3, C3-C4, C3
Middle posterior cervical region	C3-C4, C4-C5, C4
Lower posterior cervical region	C4-C5, C5-C6, C4, C5
Suprascapular region	C4-C5, C5-C6, C4

Figure 45-5 Patterns of referred pain. Patterns of reflex-referred pain from visceral and somatic structures. **A**, Anterior distribution. **B**, Posterior distribution.

reported. Throat symptoms, including dysphagia, may be related to anterior vertebral osteophytes causing direct compression, as well as to cranial nerve and sympathetic nerve communications.

Symptoms of dyspnea and cardiac arrhythmia and drop attacks may have a cervical spinal origin. Dyspnea can be related to a deficit in C3-C5 innervation of the diaphragm. Cardiac palpitations and tachycardia secondary to cervical spine pathology can be differentiated from those associated with other causes by the fact that these symptoms are associated with unusual positions or hyperextension of the neck. This is caused by irritation of C4 innervation of the diaphragm and pericardium, or by irritation of the cardiac sympathetic nerve supply. Drop attacks suggest posterior circulation insufficiency, resulting in an abrupt loss of proprioception without loss of consciousness.

Myelopathy, or spinal cord compression, initially presents with subtle complaints of hand clumsiness or difficulty with balance. Patients will report worsening handwriting in the past few months or difficulty buttoning shirts. Patients may have nausea and emesis caused by equilibrium dysfunction. Paresthesias and dysesthesias may be present, often involving bilateral upper extremities and not following a dermatomal distribution. This is often mistaken for peripheral neuropathy or carpal tunnel syndrome but should be considered when bilateral extremity symptoms are present. As the disease progresses over time, more advanced manifestations include weakness in the triceps, hand intrinsic, and hip flexors most commonly. Late manifestations include spasticity, as well as bowel and bladder dysfunction.

Finally, neck pain may present concomitant with systemic disease with varied symptoms requiring further investigation. Examples include inflammatory arthritides, infection or tumor, multiple sclerosis, subacute combined degeneration, and syrinx. Inflammatory arthritides often

present with morning stiffness, polyarticular involvement, or cutaneous manifestations. Fever, weight loss, or night pain points to an infectious or neoplastic origin. A Pancoast tumor is a neoplastic process of the apical portion of the lung that can cause a mass effect on the caudad cervical nerve roots. This should always be considered in a person with radicular symptoms and a history of smoking, with workup including a chest x-ray. Idiopathic brachial plexus neuritis, formerly known as Parsonage-Turner syndrome, is caused by viral infection of the brachial plexus presenting with severe arm pain involving multiple nerve roots. Once the acute phase resolves, patients are left with variable deficits. Subacute combined degeneration from vitamin B₁₂ deficiency is a consideration when sensory deficit is greater in the lower extremities.

Clinical Examination

A careful clinical examination provides additional focus to the differential diagnosis. The clinical examination begins broadly with observation of the patient's gait, as well as head and neck posture. Further palpation, range-of-motion testing, and neurologic examination for motor signs, reflexes, sensory signs, autonomic signs, and articular signs are performed (Table 45-4).

Careful palpation with knowledge of key anatomic bony and soft tissue landmarks in the cervical spine may localize pain to a particular cervical level and location. Anteriorly or anterolaterally, the transverse process of C1 is palpated between the angle of the jaw and the styloid process. C3 is identified by palpation of the hyoid bone. C4-C5 is at the level of the thyroid cartilage, and C6 is at the level of the cricoid ring and the carotid tubercle. In the process of examining the neck, also note the sagittal balance with retention or loss of normal cervical lordosis. Posteriorly and

Table 45-4 Nerves and Tests of Principal Muscles

Nerve	Nerve Roots	Muscle	Test
Accessory	Spinal	Trapezius	Elevation of shoulders Abduction of scapula Tilting of head to same side with rotation to opposite side
Brachial plexus	Spinal	Sternocleidomastoid	
	C5, C6	Pectoralis major	
	C7, C8, T1	Clavicular part	Adduction of arm
	C5, C6, C7	Sternocostal part	Adduction, forward depression of arm
	C4, C5	Serratus anterior	Fixation of scapula during forward thrusting of the arm
Axillary	C4, C5	Rhomboid	Elevation and fixation of scapula
	C4, C5, C6	Supraspinatus	Abduction of arm initiated
	(C4), C5, C6	Infraspinatus	External rotation of arm
	C6, C7, C8	Latissimus dorsi	Adduction of horizontal, externally rotated arm, coughing
	C5, C6	Deltoid	Lateral and forward elevation of arm to horizontal
Musculocutaneous	C5, C6	Biceps	Flexion of supinated forearm
Radial	C5, C6	Brachialis	
	C6, C7, C8	Triceps	Extension of forearm
Posterior interosseous	C5, C6	Brachioradialis	Flexion of semiprone forearm
	C6, C7	Extensor carpi radialis longus	Extension of wrist to radial side
	C5, C6	Supinator	Supination of extended forearm
	C7, C8	Extensor digitorum	Extension of proximal phalanges
	C7, C8	Extensor carpi ulnaris	Extension of wrist to ulnar side
	C7, C8	Extensor indicis	Extension of proximal phalanx of index finger
	C7, C8	Abductor pollicis longus	Abduction of first metacarpal in plane at right angle to palm
	C7, C8	Extensor pollicis longus	Extension of first interphalangeal joint
	C7, C8	Extensor pollicis brevis	Extension of first metacarpophalangeal joint
	C6, C7	Pronator teres	Pronation of extended forearm
Median	C6, C7	Flexor carpi radialis	Flexion of wrist to radial side
	C7, C8, T1	Flexor digitorum superficialis	Flexion of middle phalanges
	C8, T1	Flexor digitorum profundus (lateral part)	Flexion of terminal phalanges, index and middle fingers
	C8, T1	Flexor pollicis longus (anterior interosseous nerve)	Flexion of distal phalanx, thumb
	C8, T1	Abductor pollicis brevis	Abduction of first metacarpal in plane at right angle to palm
	C8, T1	Flexor pollicis brevis	Flexion of proximal phalanx, thumb
	C8, T1	Opponens pollicis	Opposition of thumb against 5th finger
Ulnar	C8, T1	1st and 2nd lumbricals	Extension of middle phalanges while proximal phalanges are fixed in extension
	C7, C8	Flexor carpi ulnaris	Observation of tendons during testing of abductor digiti minimi
	C8, T1	Flexor digitorum profundus (medial part)	Flexion of distal phalanges of ring and little fingers
	C8, T1	Hypothenar muscles	Abduction and opposition of little finger
	C8, T1	3rd and 4th lumbricals	Extension of middle phalanges while proximal phalanges are fixed in extension
	C8, T1	Adductor pollicis	Adduction of thumb against palmar surface of index finger
	C8, T1	Flexor pollicis brevis	Flexion of proximal phalanx, thumb
	C8, T1	Interossei	Abduction and adduction of fingers

posterolaterally, the occiput, inion, superior nuchal line, mastoid processes, and spinous processes of C2 and C7-T1 are palpable.

Soft tissues about the anterior and posterior triangles of the neck, occipital region, and posterior paraspinal muscles are examined. The sternocleidomastoid muscle is involved with whiplash injury, whereby abrupt hyperextension of the neck occurs. The muscle may be tender to palpation, or the patient may be splinting the neck with the head turned away from the injured muscle. This posturing of the neck is termed *torticollis*, and the clinician should remember that the head is turned away from the side of the involved sternocleidomastoid. Flexion injury may traumatize the trapezius muscle. Midline cervical tenderness is more of a concern with ligament injury, whereas paraspinal muscle tenderness typically is a more benign process.³⁹ The greater occipital nerves are located lateral to the inion and may be involved in traumatic inflammation associated with flexion or

extension injury resulting in suboccipital headaches. Skin markings or visible trauma should be noted at this time.

Range-of-motion examination may reveal pain or limitations in flexion-extension, lateral bending, and rotation. Flexion limitation may be assessed by the examiner placing fingers between the patient's chin and sternum at maximum flexion with 50% of the motion occurring at the occiput-C1 joint and the remaining 50% distributed over C2-C7. If the patient is unable to place the chin on the chest, the interval should be measured. One fingerwidth shows a limitation of 10 degrees, whereas three fingerwidths indicates a 30-degree limitation in flexion. On extension, the distance between the base of the occiput and the spinous process of T1 should be measured. Lateral flexion should allow the ear to touch the shoulder with motion being shared across all cervical vertebrae. On rotation, the chin should touch the shoulder with 50% of rotation occurring at C1-C2, and the remaining 50% distributed in the subaxial spine between C3 and

C7. A natural decrease in range of motion occurs with age, even in the healthy individual.⁴⁰

Range-of-motion tests the ligaments, capsules, and fascia; this motion will be reduced in the presence of cervical spinal muscular spasm or pain. Patients with degenerative changes in the cervical spine will have pain with decreased range of motion of the cervical spine without resistance. The most common findings due to changes in cervical spine articulations are as follows (in order): restriction of movement with or without pain, pain on movement, and local tenderness. Lateral flexion is the earliest and most impaired movement in degenerative diseases; rotation is first impaired in rheumatoid arthritis owing to involvement of the odontoid peg. A uniformly stiff neck may be caused by diffuse idiopathic skeletal hyperostosis (DISH), present in a quarter of elderly patients, but also may be due to ankylosing spondylosis or recent trauma to the neck.⁴¹ If articular signs are found, the examiner must evaluate the entire vertebral column and peripheral joints for evidence of further arthritis and to search for extra-articular manifestations.

Motion against resistance testing is performed after active and passive range of motion is established. Muscle groups tested include the flexors and extensors of the neck. In testing flexor muscles, a hand is placed between the forehead and the chest. The primary flexor is the sternocleidomastoid muscle; secondary flexors include the three scalene muscles and the small prevertebral muscles. Extensors are tested by placing a hand on the shoulder and head for resistance. Primary extensors include the paravertebral extensor mass, splenius, semispinalis capitis, and trapezius. Secondary flexors include the small intrinsic muscles of the neck. Rotators are examined by placing a hand on the shoulder and chin for resistance. The sternocleidomastoid muscle and the intrinsic muscles of the neck provide rotational force. Motion against resistance testing should include active maximum effort strength testing to the extremes of flexion, extension, and rotation to assess muscle

strength. Causes of decreased range of motion of the cervical spine include joint locking and bony ankylosis resulting from degenerative changes or arthritides, fibrous contractions, muscle spasm, splinting over painful joints, and nerve root or spinal cord compression or irritation. Decreased range of motion in the presence of pain or weakness warrants further investigation.

Sensation for light touch, pin prick, temperature, and proprioception should be performed. These tests are admittedly subjective; therefore both extremities should be compared to assess differences in sensation. Comparing an unaffected area such as the face with the area of decreased sensation can also be helpful. Pin prick can be performed by using a sterile needle and temperature by using an alcohol pad to assess the function of the spinothalamic tract that traverses the anterolateral aspect of the spinal cord. Light touch and proprioception assess the function of the posterior spinal column.

Dermatomes are anatomically distributed as noted in Figure 45-6. The lower extremities demonstrate a unique dermatomal map that correlates with embryologic development, whereby the limb starts in a supinated position and pronates with longitudinal growth. Perineal sensation and rectal tone are important to examine because an abnormality may indicate compression of the spinal cord or cauda equina, requiring immediate surgical intervention. Isolating the level of pathology at times can be challenging. Nerve roots with proximal compression are more susceptible to distal compression in a phenomenon termed *double crush*. The cervical spine should always be considered as the potential source in patients who present with symptoms of carpal or cubital tunnel syndrome and peripheral neuropathy. Ancillary imaging and nerve conduction studies can help elucidate the origin.

After palpation, range-of-motion testing, and assessment of sensation, muscle strength testing is continued for localization of any positive findings. Lower motor neuron disease

Figure 45-6 Dermatome distributions. Dermatome distribution of nerve fibers from C1 through T5, carrying senses of pain, heat, cold, vibration, and touch to the head, neck, arm, hand, and thoracic area. The sclerotomes and myotomes are similar but show some overlap. Pain arising from structures deep to the deep fascia (myotome and sclerotome) does not precisely follow the dermatome distribution.

Table 45-5 Strength Grading in Motor Examination

0	No function with total paralysis
1	Trace movement with palpable or visible contraction
2	Full range of joint motion with gravity eliminated
3	Active movement against gravity
4	Active movement against slight resistance
5	Normal strength

is indicated by weakness, hypotonia, and fasciculations. Upper motor neuron disease is indicated by spasticity. Motor function should be graded using the standard 0 to 5 nomenclature, with grade 0 having no function, 1 having trace, 2 having full range of joint motion with gravity eliminated, 3 having antigravity function, 4 having function against slight resistance, and 5 having normal strength against resistance (Table 45-5). If weakness is present, a more focused examination should be performed to look at other muscles innervated by that same nerve root.

Deep tendon stretch reflexes should be performed and graded 0 to 3 with 0 being no response, 1 being hyporeflexive, 2 being normal, and 3 being hyperreflexive. C5 is tested by striking the biceps tendon; C6, brachioradialis; C7, triceps; L4, patellar tendon; and S1, Achilles tendon. To facilitate reflex testing, it may be helpful to use muscle loading or Jendrassik's maneuver (performed by having the patient flex both sets of fingers into a hook-like form, interlocking the hands, and pulling apart). This creates a diversion to help relax the patient and better assess lower extremity reflexes. If difficulty with reflex testing persists, ensure that no peripheral neuropathy is present. In addition to deep tendon reflex testing, the abdominal reflex, the Babinski test, and the bulbocavernosus test should be assessed.

Provocative tests that can be helpful in confirming compressive extradural monoradiculopathy include Spurling's test, the arm abduction test, and the axial compression and traction test. All of these tests are meant to change the diameter of the neural foramen, thus increasing or decreasing the symptoms, respectively. Spurling's test is performed by having the patient extend his or her neck and rotate toward the side of pain. The test is positive if radicular pain is made worse in this position; this indicates foraminal stenosis with potential compression of a nerve root. The arm abduction sign is positive if the patient's pain is relieved by placing the hand on the affected side, on top of the head.⁴² The axial compression test is performed by pressing on top of the patient's head with the neck in neutral position; the result is positive if radicular symptoms are exacerbated by this maneuver and are relieved by placing traction on the head and opening up the foramina.

Provocative tests that are helpful in diagnosing myelopathy include the presence of Hoffmann's sign, the finger escape sign, the abnormal grip-release test, and Lhermitte's sign. Hoffmann's sign is performed by holding the middle finger extended and suddenly extending the distal interphalangeal joint, leading to flexion of the index finger and thumb if pathologic. A positive finger escape sign occurs when an individual cannot hold all fingers in an adducted and extended position without the ulnar two digits falling into flexion and abduction over time. The grip-release test is an inability to rapidly open and close a fist caused by weakness and spasticity of the hand. Lhermitte's sign

evaluates for changes in the spinal cord itself and occurs when the patient's neck is forcefully flexed, resulting in electric-like shocks that travel down the arms and legs. This indicates changes in the white matter of the spinal cord and may occur secondary to cervical myelopathy or multiple sclerosis.

DIAGNOSTIC EVALUATION

After the history and clinical examination are completed, imaging studies, neurophysiologic procedures, and laboratory studies may aid in completing the differential diagnosis and building a treatment plan for the patient's neck pain. Cervical radiographs often show degenerative changes in asymptomatic individuals in their 60s.⁴³ In the absence of trauma, constitutional symptoms, or worsening neurologic deficit, 4 to 6 weeks of conservative care is indicated before radiographs are obtained.⁴⁴ Dynamic radiographs should also be used for screening patients with rheumatoid arthritis before endotracheal intubation, given the risk of cervical instability. One study demonstrated that 61% of patients with RA had evidence of instability defined by at least 3 mm of atlantoaxial subluxation on preoperative screening x-rays.⁴⁵

In the presence of significant degenerative changes and end plate osteophytes, CT myelography can be helpful in further characterizing bony involvement. CT myelography should be thought of as a complementary test to magnetic resonance imaging (MRI).⁴⁶ It should be used as the primary test to evaluate neural involvement only when MRI is contraindicated, because MRI is superior for evaluating spinal cord changes such as syringomyelia, myelomalacia, or neoplasm.⁴⁷ MRI scanning is indicated for progressive neurologic deficit, disabling weakness, or long tract signs and is recommended for patients with persistent cervical radiculopathy after 6 weeks of conservative care.⁴⁴ The addition of gadolinium contrast enhancement is helpful in evaluating infection and neoplasm, and in differentiating scar from recurrent disk herniation in patients who have undergone previous spinal surgery. MRI results must be correlated with physical examination findings given that asymptomatic volunteers have been found to have abnormal cervical spine MRI.⁴⁸ Increased signal on T2 sequence can be representative of a spectrum of disease from edema to myelomalacia and syrinx formation. Therefore the presence of increased signal within the spinal cord warrants a surgical consultation, and operative intervention, or close follow-up at a minimum, is provided if examination and history correlate. If MRI findings do not correlate with the history and physical examination findings, additional studies such as CT myelography may be required. CT myelography is superior for detecting bony foraminal stenosis. Nuclear bone scanning techniques, including single-photon emission computed tomography (SPECT) scans, have been used to identify and characterize acuity in occult fracture, periosteal injury, and posttraumatic osteoarthritis in the absence of positive radiograph findings.⁴⁹

Neurophysiologic procedures are indicated when the clinical examination and imaging studies fail to correlate, or when there is conflicting information. Electromyography (EMG), nerve conduction studies (NCSs), and somatosensory evoked responses (SERs) help differentiate cervical

spine disorders from peripheral nerve entrapment syndromes and help in differentiating intrinsic joint pathology from a radiculopathy. These tests are complementary to plain radiographs and an MRI or CT myelogram.

Neck pain typically occurs secondary to mechanical causes, and laboratory studies generally are not helpful in its diagnosis. However, laboratory studies can be critical in ruling out infection, neoplasm, and systemic arthritides. Erythrocyte sedimentation rate (ESR) indirectly measures the acute phase response with high sensitivity but low specificity. Patients younger than age 50 should have an ESR less than 20 mm/hr, with the accepted normal range increasing as the patient ages. Values above 100 are seen with infection and neoplasm, whereas less dramatic elevations are seen with rheumatoid arthritis and following surgery.⁵⁰ C-reactive protein (CRP) is an acute phase reactant synthesized by the liver; elevations peak by day 2 of the inciting event and return to normal within 3 to 7 days of removal of the insult.⁵¹ Complete blood count (CBC) with differential and spinal tap can be helpful if meningitis is a concern.

DIFFERENTIAL DIAGNOSIS AND TREATMENT

By using the history, physical examination findings, and diagnostic studies, it is helpful to divide the differential diagnosis into benign axial neck pain, radiculopathy, myelopathy, infection, neoplasm, systemic arthritides, and referred pain. Most axial neck pain is self-limiting and will resolve with appropriate conservative care.⁵² Axial neck pain with associated radiculopathy has a fairly benign course; 75% of patients have only one recurrence or mild symptoms at 19 years' follow-up with conservative treatment.⁵³ Patients with isolated neck pain and a negative radiographic and laboratory workup are best treated with a multimodal approach. During the acute phase, patients can be treated with a soft collar to reduce inflammation, but this should not be worn for longer than 2 weeks so as to avoid deconditioning. Multimodal treatments, including proprioceptive training, exercise with resisted strengthening, muscle relaxers during the acute period, and nonsteroidal anti-inflammatory drugs (NSAIDs), have been found to be most effective in treating axial neck pain.⁵⁴⁻⁵⁹ Evidence is inconclusive as to the effectiveness of radiofrequency denervation of facet joints, acupuncture, transcutaneous electrical nerve stimulation (TENS) treatment, iontophoresis, EMG biofeedback, or local injections for treatment of axial neck pain.⁶⁰⁻⁶³

Cervical traction may be prescribed; a typical regimen includes 8 to 10 pounds for sessions of 15 to 20 minutes with the device at 20 to 25 degrees of flexion. However, this has resulted in only short-term relief of radicular symptoms.⁶⁴ Fluoroscopically guided interlaminar and transforaminal epidural steroids have been shown to be effective in treating lumbar radiculopathy, but this has not been shown in the cervical spine.⁶⁵ Cervical injections carry a higher risk, with complications, including neurologic deficits, reported in up to 16% of patients.^{66,67} Given these increased risks with epidural steroid injections in the cervical spine, a more conservative approach should be taken in prescribing this treatment modality. Atlantoaxial facet joint osteoarthritis

may be treated successfully with a facet block and nonsteroidal anti-inflammatory medications. If conservative therapy with NSAIDs fails, a fusion may be indicated.

In addition to degenerative changes to the cervical spine, trauma, and acute disk herniation, more insidious causes of neck pain include schwannoma, Pancoast tumor, brachial plexus neuritis, and complex regional pain syndrome. Schwannomas, if intradural, may involve a sensory nerve root, causing dermatomal pain in addition to a myelopathy or radiculopathy from compression. Pancoast tumor involving the lung apex may cause caudal cervical nerve root and sympathetic changes, in addition to nerve root or brachial plexus compression. Brachial plexus neuritis (Parsonage-Turner syndrome) is of viral origin, causing severe arm pain followed by weakness and then pain resolution; return of arm strength follows. This condition may progress to complex regional pain syndrome, along with autonomic changes such as discoloration of the skin, in a small number of cases associated with diffuse burning pain.

Follow-up and vigilance are in order because a progressive neurologic deficit, segmental instability, or persistent radicular symptoms for at least 6 weeks may be indications for surgical intervention. In a prospective randomized study comparing surgery, physical therapy, and cervical collar use for long-standing cervical radiculopathy, no difference was found between the three groups at 12 months.⁶⁸ Cervical myelopathy with very mild deficits can be followed closely; however, the natural course of the illness consists of long periods of stability with episodes of deterioration. Definitive indications for surgery include the presence of myelopathy for 6 months or longer, progression of signs or symptoms, difficulty walking, or changes in bowel or bladder function. Surgery is directed at decompressing the spinal cord and preventing further deterioration, rather than improving neurologic deficits.

Systemic arthritides, infection, and tumors can affect the cervical spine with variable neurologic and constitutional symptoms. Rheumatoid arthritis typically causes atlantoaxial subluxation, atlantoaxial impaction, and subaxial subluxation (Table 45-6). Surgical stabilization is indicated

Table 45-6 Rheumatologic Disorders Causing Neck Pain

Rheumatoid arthritis
Without disease of the C1-C2 joint
With structural cervical abnormalities
C1-C2 subluxation
C1-C2 facet involvement
Spondyloarthropathies
Ankylosing spondylitis
Reactive arthritis
Psoriatic arthritis
Enteropathic arthritis
Polymyalgia rheumatica
Osteoarthritis
Fibromyalgia
Nonspecific musculoskeletal pain
Miscellaneous spondyloarthropathies
Whipple's disease
Behçet's disease
Paget's disease
Acromegaly
Ossification of the posterior longitudinal ligament
Diffuse idiopathic skeletal hyperostosis

with progressive neurologic deficit, persistent axial neck pain with radiographic evidence of instability, canal diameter of 14 mm or less (posterior atlanto-dens interval), and odontoid migration of 5 mm or greater above McGregor's line. In the setting of atlantoaxial subluxation or subaxial subluxation, the involved levels are fused posteriorly, and atlantoaxial impaction should be treated with occipitocervical fusion.⁹ Rheumatoid patients with evidence of instability demonstrate radiographic progression over time, but this correlates poorly with neurologic outcome.⁶⁹ Regardless, these patients require close follow-up given that once myelopathy develops, most patients die within 1 year.⁷⁰

Ankylosing spondylitis commonly affects the cervical spine, resulting in a kyphotic deformity over time with altered biomechanics; this has implications in the setting of trauma. The kyphotic deformity can have significant functional implications because the person's gaze moves toward the floor, making interaction with the surrounding world difficult. Corrective osteotomies are available, but risks include neurologic deficit and intraoperative bleeding. Hopefully, earlier diagnosis with the use of MRI and treatment with tumor necrosis factor–blocking agents will help make cervical deformity a thing of the past.⁷¹

Both infection and neoplastic processes can cause destruction with mechanical or nonmechanical neck pain, constitutional symptoms, and variable neurologic deficit. The goals of treatment are similar in both with eradication of the infection or tumor, decompression if a neurologic deficit exists, and stabilization of the spinal column.

In summary, a careful history and physical examination and ancillary studies will help one arrive at a fairly narrow differential diagnosis. In the absence of spinal instability, neurologic deficit, and infectious or neoplastic processes, the patient may benefit from conservative treatment with expectant recovery with a "tincture of time."

KEY POINTS

Comprehension of functional anatomy allows diagnosis of most causes of shoulder pain on clinical examination.

History and clinical examination aided by ancillary tests will usually guide application of the most appropriate treatment for shoulder pain.

The differential diagnosis of shoulder pain includes not only common local disorders (e.g., of tendon and adjacent structures) but should also include consideration of etiologies arising from distant anatomic sites arising by referred pain-mediated pathways.

A variety of specific diagnostic tests can greatly aid in diagnosis of shoulder pain.

Most causes of shoulder pain can be treated with a structured physical therapy program. Successful treatment programs understand potential surgical candidates including those who fail conservative treatment.

Systemic arthropathies can occasionally present with shoulder disease and often involve the shoulder over time. Early assessment in such patients is essential.

Shoulder pain is one of the most common musculoskeletal complaints that may arise from diverse causes. Accurate diagnosis of shoulder pain is made difficult by the unique anatomy and position of the shoulder, which serves as a link between the upper extremity and the thorax. One of the most complex and mobile joints of the body, the shoulder is traversed by muscle, tendon, and bone, and is surrounded by major neurovascular structures, all of which may serve as potential sources of local and referred pain.

Determining the source of shoulder pain is essential in recommending the proper method of treatment. The examining physician must be able to differentiate the occurrence of shoulder pain caused by intrinsic, or local factors, and extrinsic, or remote factors, or a combination of the two. Intrinsic factors originate from the shoulder girdle and include glenohumeral and periarticular disorders, whereas extrinsic factors occur outside of the shoulder girdle with secondary referral of pain to the shoulder (Table 46-1). Examples of extrinsic factors include left shoulder pain as the initial presentation of coronary artery disease; hepatic, gallbladder, and splenic disease also may initially manifest as shoulder pain.

Accurate evaluation, diagnosis, and treatment require a thorough understanding of shoulder anatomy, including pain referral patterns. A complete and systematic physical examination is crucial for an accurate diagnosis. During the initial evaluation, care must be taken to discern all possible

Shoulder Pain

SCOTT DAVID MARTIN •
THOMAS S. THORNHILL

causes of shoulder pain. Final diagnosis may require repeated office examinations and correlation of diagnostic tests with symptoms and response to selective injections. Improvements in diagnostic tests, such as magnetic resonance imaging (MRI), computed tomography (CT)-arthrography, ultrasonography, and electromyography (EMG), have facilitated early diagnosis of shoulder pain and have provided a better understanding of shoulder pathology.

This chapter provides practical guidelines for the diagnosis and treatment of painful shoulder disorders that may be encountered in a rheumatology or general practice. A detailed analysis of shoulder problems and information on the treatment of major trauma are beyond the scope of this chapter and have been addressed by other authors.

ANATOMY AND FUNCTION

Because of its complexity, an understanding of the structural and functional anatomy of the shoulder is required for the clinician who is treating shoulder pain. The shoulder joint is the most mobile joint of the body, although mobility is gained at the sacrifice of stability. Only 25% of the humeral head surface has contact with the glenoid at any time. The labrum increases the contact area of the articular surface and confers stability to the joint.⁶ Lesions of the labrum may result from instability, and the type of lesion may indicate the type of instability. Labral tears also may be a source of pain from internal derangement of the shoulder.⁷ Joint stability is provided by a thin capsule and by the glenohumeral ligaments, which are thickenings of the capsule anteriorly, posteriorly, and inferiorly.⁶ Anterior stability is predominantly conferred by the anterior band of the inferior glenohumeral ligament.

The rotator cuff provides dynamic stability of the joint. It is composed of four musculotendinous units: the supraspinatus, infraspinatus, and teres minor posteriorly, and the subscapularis anteriorly. The shoulder consists of three joints: the acromioclavicular (AC), sternoclavicular, and glenohumeral joints, and two gliding planes—the scapulothoracic and subacromial surfaces.

Figure 46-1 shows the musculoskeletal and topographic localization of pain associated with common shoulder disorders. Figure 46-2 shows the relationship of the three posterior rotator cuff muscles coursing anteriorly underneath the acromion to insert on the greater tuberosity. The subscapularis, the only anterior rotator cuff muscle, inserts on the lesser tuberosity. By understanding the relationship between the rotator cuff and the subacromial region, bounded inferiorly by the humeral head and superiorly by the undersurface of the acromion, the clinician can visualize the problems of impingement syndrome and can accurately

Table 46-1 Common Causes of Shoulder Pain

inject this space. Knowledge of the route of the tendon of the long head of the biceps through the bicipital groove and onto the superior aspect of the glenoid helps in understanding bicipital tendinitis. Before attempting to diagnose and treat shoulder pain, the clinician should review in detail one of the many sources describing the structural and functional relationships of the shoulder girdle.^{2,3}

DIAGNOSIS

Clinical Evaluation of the Shoulder

Accurate diagnosis and successful treatment of a shoulder disorder begin with a thorough history and physical examination. Most of the information needed to make a correct diagnosis can be elicited with basic clinical skills, rather than by relying on expensive and highly technologic investigative aids. Diagnostic tests should be used only to confirm an established diagnosis or to assist in cases with a challenging presentation.

History

In establishing a diagnosis, it is important to consider the patient's age and chief complaint. The differential diagnosis of shoulder pain in a 70-year-old sedentary individual is entirely different from that in a 20-year-old pitcher. Did the pain occur slowly over time or suddenly with a particular

event? Gradual onset of pain over the anterolateral or deltoid region that is increased with forward elevation of the shoulder and nocturnal pain suggest impingement with rotator cuff tendinopathy. The presence of significant weakness with pain on overhead activities suggests impingement with rotator cuff tear. Pain and weakness may also be noted with reaching behind the back with the shoulder in extension and external rotation, as when reaching into the back seat of a car. Initiating factors relative to the onset of symptoms should be elicited, and any history of shoulder pain or trauma should be carefully documented.

Pain intensity, character, location, and periodicity and aggravating or alleviating factors should be assessed. Pain should be graded on a visual analog scale of 0 to 10, with 0 indicating no pain, and 10 indicating the worst pain the patient has ever experienced. Another indication of the severity of pain is disruption of sleep. The patient should be asked whether the pain prevents sleep or awakens the patient, and whether the patient can lie on the affected shoulder. Is the pain sharp or dull? Sharp, burning pain over the top of the shoulder indicates a neurogenic origin, whereas a dull, aching pain over the lateral deltoid suggests rotator cuff pathology with impingement. Location or distribution of the pain should be identified. Is it local around the shoulder girdle, or does the pain radiate down the arm? Is concomitant sensory loss or weakness present? Periodicity of the pain as constant or intermittent should be determined, as should factors that aggravate or alleviate the pain. Pain caused by rotator cuff tendinopathy usually is exacerbated by repetitive activities that involve the elbow away from the side of the body.

Any history of neck pain should be considered, along with history of radicular pain. Radicular-type pain frequently extends below the elbow and is associated with sensory loss and weakness. Pain located in the paracervical region may indicate a cervical origin, or it can be localized to the trapezius. Trapezial pain often is associated with shoulder pain and results from the patient trying to favor the shoulder. Assuming a military brace position may produce fatiguing, spasm, and trigger points of the trapezius.

Any pertinent medical history, such as a history of malignancy, should be considered. Neurologic, visceral, and vascular disease can produce referred pain to the shoulder and should always be considered, especially in a patient with a painless range of motion.

Physical Examination

Proper physical examination of the shoulder includes close inspection of the shoulder girdle from the front and back. The evaluation is started by standing behind the patient, who has both shoulders exposed. The normal shoulder is always inspected and compared with the injured shoulder. Examination can be performed with the patient in the sitting or standing position. Contour and symmetry are observed and compared between shoulders, and any atrophy or asymmetry in shoulder position or level is assessed. Spinatus muscle atrophy may result from disuse, chronic cuff tear, or suprascapular or brachial neuropathy.⁸ If scapular winging is evident, the patient should be asked to do a wall push-up, which accentuates winging.

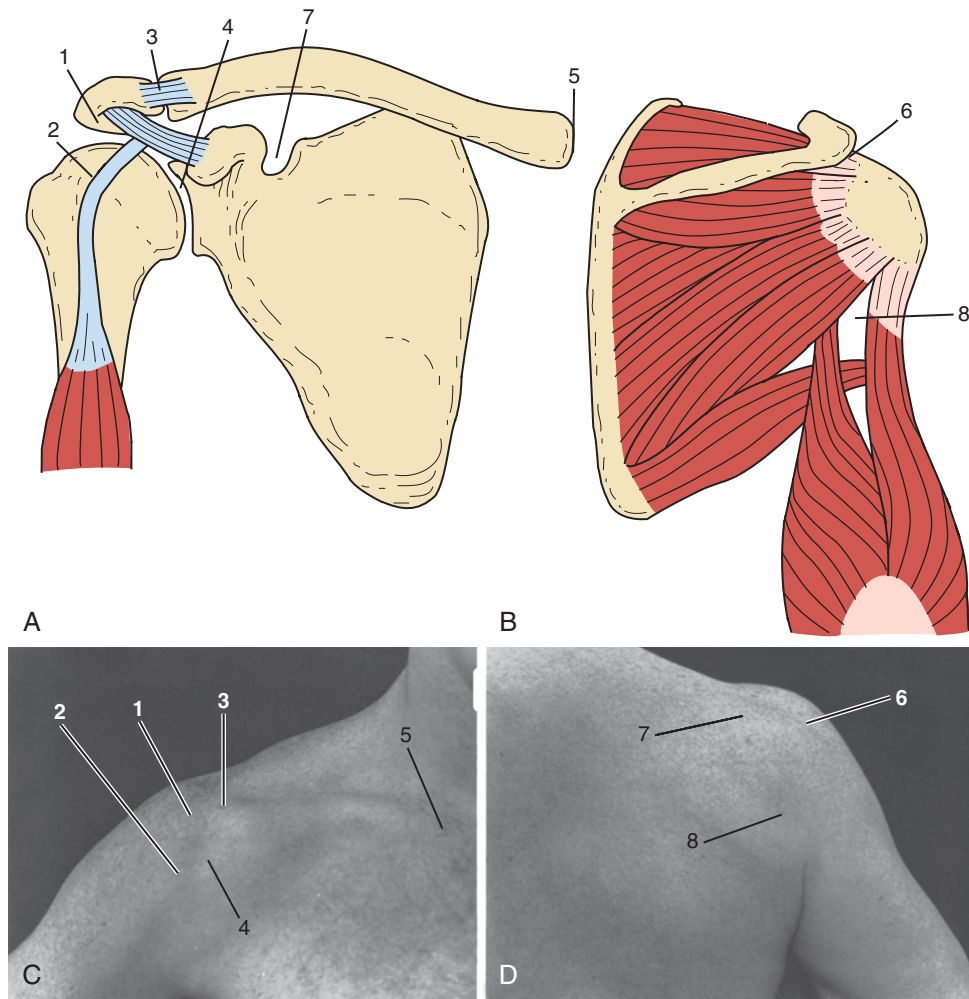

Figure 46-1 Musculoskeletal (A and B) and topographic (C and D) areas localizing pain and tenderness associated with specific shoulder problems. 1, Subacromial space (rotator cuff tendinitis/impingement syndrome, calcific tendinitis, rotator cuff tear). 2, Bicipital groove (bicipital tendinitis, biceps tendon subluxation and tear). 3, Acromioclavicular joint. 4, Anterior glenohumeral joint (glenohumeral arthritis, osteonecrosis, glenoid labrum tears, adhesive capsulitis). 5, Sternoclavicular joint. 6, Posterior edge of acromion (rotator cuff tendinitis, calcific tendinitis, rotator cuff tear). 7, Suprascapular notch (suprascapular nerve entrapment). 8, Quadrilateral space (axillary nerve entrapment). These areas of pain and tenderness frequently overlap.

Figure 46-2 A, Superior view of the rotator cuff musculature as it courses anteriorly underneath the coracoacromial arch to insert on the greater tuberosity. B, Anterior view of the shoulder reveals the subscapularis, which is the only anterior rotator cuff muscle inserting on the lesser tuberosity. It internally rotates the humerus and provides dynamic anterior stability to the shoulder. (A and B, From the Ciba Collection of Medical Illustrations, Volume 8, Part I. Netter Illustration from www.netterimages.com ©Elsevier Inc. All rights reserved.)

Range of motion should be carefully recorded, along with notation of any absence of rhythmic shoulder motion or excessive scapulothoracic motion that may compensate for the lack of glenohumeral motion. Internal rotation of the shoulder is checked by having the patient reach behind the back with the thumb while the examiner notices the vertebral level. Loss of internal rotation is seen early with shoulder pain and usually indicates some tightness of the posterior shoulder capsule. The biceps tendon; the coracoid, lesser, and greater tuberosities; and the posterior cuff are palpated, and any tenderness is gauged (Figure 46-3A). Tenderness on palpation of the long head of the biceps frequently is associated with rotator cuff tendinopathy and tenderness of the greater tuberosity. Any spasm or tenderness of the trapezius or levator scapulae may be associated with rotator cuff disease or cervical spine disease. Cervical range of motion and palpation of the paracervical muscles are carried out. Paracervical tenderness and limited range of motion of the neck may indicate cervical spondylosis or neurogenic disease. A Spurling test is done by flexing the neck laterally

while applying axial compression to the skull. Pain that radiates to the ipsilateral shoulder is considered a positive test result and indicates radiculopathy.

To elicit the impingement sign, the shoulder is elevated passively in forward flexion, while the scapula is depressed with the opposite hand, forcing the greater tuberosity against the anterior acromion and producing pain in cases of impingement (Figure 46-3B).⁹ This maneuver also may be painful in conditions such as adhesive capsulitis, glenohumeral and acromioclavicular (AC) arthritis, glenohumeral instability, and calcific tendinitis. A dynamic impingement test, the circumduction-adduction shoulder maneuver, also called the Clancy test, is 95% sensitive and 95% specific for diagnosing rotator cuff tendinopathy, including partial tears.¹⁰ The test is done with the patient in the standing position and with the head turned to the contralateral shoulder. The affected shoulder is circumducted and adducted across the body to shoulder level, while the elbow is kept in extension, the shoulder in internal rotation, and the thumb pointing toward the floor

Figure 46-3 A, Tenderness on palpation of trigger points may help localize the site of pathology. Tenderness on palpation of the long head of the biceps and greater tuberosity suggests impingement with possible cuff tendinopathy. B, To elicit the impingement sign, the shoulder is elevated in forward flexion while the scapula is depressed with the opposite hand, forcing the greater tuberosity and the rotator cuff against the anterior acromion and producing pain when impingement exists. Relief of pain after injection of local anesthetics (i.e., impingement test) provides additional evidence of subacromial pathology. C, The Clancy test is performed with the patient standing and with the head turned toward the contralateral shoulder. The affected shoulder is circumducted and adducted across the body to shoulder level, keeping the elbow in extension with the arm internally rotated with the thumb pointed toward the floor. In this position, the patient is asked to resist maximally as a uniform downward force is applied to the extended arm by the examiner. Production of pain or weakness localized to the anterior lateral portion of the shoulder is considered a positive test result. D, The test is performed by forward flexion of the arm at 90 degrees and subsequent cross-chest adduction of the arm. Pain localized to the acromioclavicular joint is considered a positive test result. E, The test is performed with the patient's elbow flexed at 90 degrees and held at the patient's side by the examiner. The patient is asked to attempt external rotation of the shoulder from a neutral position (0 degrees of adduction) as the examiner applies resistance to the forearm. Strength is compared with that of the contralateral arm. F, Abduction strength testing is performed with the patient's shoulder in 30 degrees of forward flexion and 90 degrees of abduction and with the thumb pointed toward the floor. The patient is asked to resist as the examiner exerts a downward force on the abducted arm. Strength is compared with the contralateral shoulder. (From Martin TL, Martin SD: Rotator cuff tendinopathy, *Hosp Med* 12:23–31, 1998.)

(Figure 46-3C). In this position, the patient is instructed to resist maximally as a uniform downward force is applied to the extended arm by the examiner. The test result is considered positive if pain or weakness is elicited during the maneuver, with pain localized to the anterolateral aspect of the shoulder. A strong positive correlation of pain and weakness is noted with complete cuff tear.¹⁰

The sternoclavicular and AC joints should be observed for prominences and palpated for stability and tenderness. Many patients with impingement have tenderness on direct downward palpation of the AC joint owing to impingement on the cuff from undersurface osteophytes of the distal clavicle.^{2,8}

AC joint tenderness may also result from primary AC joint arthrosis and should be differentiated by physical examination, including the cross-chest adduction test and O'Brien's test.¹¹ Radiographic evidence of AC joint arthrosis is common in patients older than 40 years, but this condition is not usually painful.¹²

The cross-chest adduction test or the horizontal adduction test is performed by forward flexing the shoulder 90 degrees with subsequent cross-chest adduction of the arm (Figure 46-3D). Pain localized to the AC joint is considered a positive test result. If pain occurs posteriorly over the shoulder, a tight posterior capsule with impingement is suspected. O'Brien's test is performed by forward flexing the arm 90 degrees and adducting the arm 10 degrees out of the sagittal plane of the body. The first part of the test is performed with the hand maximally pronated with the thumb pointed down. In this position, the patient is asked to resist as the examiner applies a downward force on the arm. If the test elicits pain, the patient is asked if the pain is on top of the shoulder or deep inside. Pain localized to the top of the shoulder indicates AC joint pain, and pain deep inside the shoulder indicates a superior labrum anterior posterior (SLAP) lesion. In the second part of the test, the patient is asked to supinate the hand maximally, while the examiner applies a downward force to the arm. If the patient notices significantly less pain, the test result is positive for a SLAP lesion. If the pain is unchanged and is located on top of the shoulder, the test result is positive for AC joint pathology.¹¹

If the cause of AC joint tenderness is still in question, a lidocaine injection should be administered. The clinician should carefully avoid injecting the subacromial space by advancing the needle too far inferiorly through the AC joint; this can lead to false interpretation. Painful degenerative changes of the AC joint may exist concomitantly with subacromial impingement and should be evaluated thoroughly when surgical treatment (i.e., distal clavicle excision) is being considered.¹³

In patients with pain out of proportion to objective findings, other causes of shoulder pain should be sought, including calcific tendinitis, infection, reflex sympathetic dystrophy, and fracture. Patients with significant wasting of the supraspinatus and infraspinatus muscles and posterior shoulder pain, especially younger patients, may have suprascapular neuropathy or brachial neuropathy (Parsonage-Turner syndrome).^{8,14}

Patients with chronic cuff disease frequently have variable disuse atrophy of the supraspinatus and infraspinatus fossae; in cases of chronic massive cuff tears, atrophy and

weakness can be severe. Strength testing of external rotation should be done with the elbow at the side and supported by the examiner; the patient is asked to attempt external rotation of the shoulder from a neutral position (0 degrees of adduction), while the examiner applies resistance (Figure 46-3E).¹⁵ Weakness in this position may suggest a tear of the infraspinatus tendon. Abduction strength testing against resistance is done with the shoulder in 30 degrees of forward flexion and 90 degrees of abduction, and with the thumb pointed toward the floor (Figure 46-3F).^{16,17} Weakness in this position may suggest a tear of the supraspinatus tendon. A lift-off test should be performed with the shoulder in internal rotation; the patient is asked to try to hold the hand away from the back. Inability to do so indicates a subscapularis tear.

If after a thorough physical examination impingement is suspected, an impingement test should be performed with injection of 5 mL of local anesthetic into the subacromial space.^{18,19} Before the test is performed, the patient is asked to grade the pain during the impingement signs on a visual analog scale of 0 to 10, with 0 equal to no pain and 10 equal to the most severe pain the patient has ever experienced. The injection may be done anteriorly, laterally, or posteriorly, depending on the physician's preference. Ten minutes after injection of local anesthetic into the subacromial space, the patient should be re-examined and asked to regrade the pain on the same visual analog scale. A 50% or greater reduction in pain is thought to be a positive test result for impingement; otherwise, an alternative cause of shoulder pain should be sought, or inadequate placement of the anesthetic should be suspected. If the AC joint is thought to be contributing to the shoulder pain, 1 to 2 mL of local anesthetic should be injected into the joint, and the shoulder should be re-examined. When subacromial impingement and the AC joint are thought to be contributing to shoulder pain, serial injections during separate office visits may be needed to evaluate the shoulder while minimizing discomfort to the patient.¹²

In cases of suspected bicipital tendinitis, Speed's test is performed by having the patient flex the shoulder and extend the elbow while a downward force is applied to the arm. The production of pain over the long head of the biceps is a positive test result and suggests bicipital tendinitis.

Upper extremity strength testing should be performed and compared with the contralateral side so that any atrophy is detected. Grip strength is checked, and the hands are examined carefully for evidence of intrinsic atrophy. The biceps (C5), triceps (C7), and brachioradialis (C6) reflexes are checked for symmetry and briskness.

Light touch sensory testing should be conducted, and the dermatomal distribution of any deficits that may suggest cervical radiculopathy should be identified. The cervical, supraclavicular, axillary, and epitrochlear regions should be palpated for enlarged lymph nodes, which may suggest malignancy.

Imaging

Radiographic Assessment

For nontraumatic painful shoulder evaluation, standard radiographic profiles are used. An impingement series

should be obtained, which includes anteroposterior views with a 30-degree caudal tilt (Rockwood view), an outlet view (scapular Y with 10- to 15-degree caudal tilt), and an axillary view. Internal and external rotational views may be obtained if calcific tendinitis or instability is suspected. The Rockwood view can reveal any osteophytes off the anterior acromion and AC joint.²⁰ In cases of traumatic injury, a trauma series is obtained that includes a true anteroposterior view, a scapular Y view, and an axillary view. The axillary view is useful in assessing posterior or anterior subluxation of the humeral head. Additional views, such as the West Point view, which evaluates the glenoid for evidence of a bony Bankart lesion, or the Styker notch view, which assesses the humeral head for a Hill-Sachs lesion, may be obtained to assist evaluation if the diagnosis of instability is in doubt. Secondary impingement-type rotator cuff tendinitis may be caused by increased anterior translation with subluxation of the humeral head. In such cases, an axillary view or fluoroscopy can help show the subluxation.^{21,22}

When AC joint pathology is suspected, a 10-degree, cephalic tilt view of the AC joint at 50% penetrance, as described by Zanca,²³ should be obtained (Figure 46-4). Stress views of the AC joint may be obtained by strapping 5 to 10 lb of weight to the patient's forearms and determining AC separation. Comparing the coracoclavicular distance of both shoulders may be helpful. When clinically indicated, cervical spine radiographs should be obtained to exclude cervical spondylosis as a cause of shoulder pain.

Scintigraphy

Tc 99m methyl diphosphonate (MDP) or gallium may be of diagnostic help in evaluating skeletal lesions around the shoulder joint. Bone scans generally are not helpful in the

Figure 46-4 Zanca view of the acromioclavicular joint is obtained with a 10-degree cephalic tilt and 50% penetrance. (From Rockwood CA Jr, Young DC: *Disorders of the acromioclavicular joint*. In Rockwood CA Jr, Matsen TA III, editors: *The shoulder*, Philadelphia, 1985, WB Saunders, pp 413–476.)

Figure 46-5 Normal double-contrast arthrography shows the inferior edge of the rotator cuff (RC) as it courses through the subacromial space to the greater tuberosity, the tendon of the long head of the biceps (BT), and the articular cartilage of the humeral head (AC).

diagnosis of non-neoplastic or noninfectious shoulder disease.

Scintigraphy may have a role in identifying patients with complete rotator cuff tears that proceed to cuff-tear arthropathy. This is an important distinction because patients with complete rotator cuff tears may do well, whereas those who develop progressive changes of cuff-tear arthropathy have progressive arthritis, pain, and significant functional impairment. Synovitis or calcium pyrophosphate deposition disease may be an important factor in the pathogenesis of cuff-tear arthropathy. In such cases, scintigraphy may show the increased blood flow and blood pooling associated with chronic synovitis.

Arthrography

Double-contrast arthrotomography (DCAT) can be used to evaluate problems of the rotator cuff, glenoid labrum, biceps tendon, and shoulder capsule.²⁴⁻²⁷ Figure 46-5 shows normal DCAT of the shoulder. Rotator cuff tears can be shown by single-contrast or double-contrast studies. Proponents of double-contrast arthrography believe that the extent of the tear, the preferred surgical approach, and the quality of the rotator cuff tissue are best determined by double-contrast studies.²⁴⁻²⁹ Arthrography without MRI or CT can be misleading and may result in underestimation of the extent of a rotator cuff tear. Multidetector CT can enhance the accuracy of diagnosing labral and rotator cuff tears, especially in patients for whom MRI is not possible (Figure 46-6).

Tears of the glenoid labrum without shoulder dislocation are sources of anterior shoulder pain in athletes.⁷ Glenoid labrum tears (Figure 46-7), with or without associated glenohumeral subluxation, frequently can be identified by DCAT.^{27,28} Kneisl and colleagues³⁰ described 55 patients who underwent DCAT followed by diagnostic shoulder

Figure 46-6 Multidetector computed tomography revealing a superior labral tear of the shoulder.

arthroscopy. DCAT predicted the arthroscopic findings in 76% of anterior labrum studies and 96% of posterior labrum studies. This test was 100% sensitive and 94% specific in diagnosing complete rotator cuff tears. Partial rotator cuff tears identified at arthroscopy were missed in 83% of patients undergoing DCAT. Investigators believed that DCAT was better in diagnosing intra-articular and cuff pathology in cases of instability than when pain alone was the presenting diagnosis.³⁰

Shoulder arthrography can confirm a diagnosis of adhesive capsulitis by showing a contracted capsule with an obliterated axillary recess (Figure 46-8). The use of subacromial bursography has been beneficial in visualizing the outer surface of the rotator cuff and the subacromial space in cases of impingement.^{31,32} Fukuda and associates³³ reported a small series of younger patients (average age, 41.8 years) who underwent subacromial bursography after a negative glenohumeral arthrographic result. These patients showed pooling of contrast medium on the bursal side of a tear, which was confirmed at the time of surgery. Subacromial

Figure 46-7 Double-contrast arthrotomography shows a tear of the anterior-inferior portion of the glenoid labrum (arrow).

Figure 46-8 Double-contrast arthrography of a patient with calcific tendinitis (arrow) and adhesive capsulitis. Notice the contracted capsule with diminution of the synovial space and obliteration of the axillary recess.

bursography is not routinely used diagnostically, and, in our opinion, it is of little value in planning surgical procedures.

Computed Tomography

CT is helpful in evaluating the musculoskeletal system, and CT combined with contrast arthrography (CT-arthrography) has become a major diagnostic tool for the evaluation of glenoid labrum tears, loose bodies, and chondral lesions (Figure 46-9). Rafi and co-workers³⁴ reported using CT-arthrography in an evaluation of shoulder derangement. This study found 95% accuracy of CT-arthrography for investigating lesions of the labrum and articular surface.³⁴ More recently, multidetector CT-arthrography scans have been used to evaluate partial cuff tears (Figure 46-10A), cystic lesions (Figure 46-10B), and calcific tendinopathy (Figure 46-10C).

Ultrasonography

Technologic improvements in ultrasound equipment have led to improved ultrasound study of the rotor cuff. The technique is noninvasive, is rapid, and involves no radiation exposure.^{30-32,35} The cuff is examined in the horizontal and transverse planes with the arm in different positions to allow visualization of various areas of the cuff. These techniques generally provide visualization of the distal cuff, where most rotator cuff tears are located. Figure 46-11 shows normal and abnormal ultrasound images of the rotator cuff in longitudinal and transverse planes.

Several studies report high sensitivity and specificity for the diagnosis of a rotator cuff tear by ultrasound.³²⁻³⁵ The specificity and sensitivity of the procedure are reported to be greater than 90% as determined by arthrographic and surgical correlations.^{34,35} This technique also has been used for the postoperative evaluation of a rotator cuff repair and for evaluation of abnormalities of the biceps tendon.³⁶⁻⁴⁰

Figure 46-9 CT-arthrography of the shoulder. **A**, Normal findings. **B**, Tear of the anterior glenoid labrum. **C**, Large defect of the articular surface of the posterior portion of the humeral head (Hill-Sachs lesion) (arrow). **D**, Loose body in the posterior recess (arrow).

Gardelin and Perin⁴¹ reported ultrasound to be 96% sensitive in determining rotator cuff and biceps tendon pathology. Mack and associates³⁶ found ultrasound to be valuable in evaluating postoperative patients with recurrent shoulder symptoms. In a prospective study, Hodler and colleagues³⁹ compared ultrasound with MRI and arthrography in evaluating rotator cuff lesions in 24 shoulders. Ultrasound identified 14 of 15 torn cuffs, MRI identified 10 of 15, and arthrography identified 15 of 15.³⁹ Ultrasound identified 7 of 9 intact rotator cuffs, whereas MRI was accurate in 8 of 9 intact cuffs.³⁹ Vestring and colleagues⁴² found ultrasound to be as accurate as MRI in the diagnosis of humeral head defects and joint effusions, but inferior to MRI in the diagnosis of labrum lesions, rotator cuff lesions, subacromial spurs, and synovial inflammatory disease. In the hands of an experienced sonographer, ultrasound may be the most cost-effective test for the initial evaluation of a rotator cuff injury, but most surgeons require CT-arthrography or MRI confirmation before beginning surgical exploration.^{36,39,41-43}

Arthroscopy

The use of arthroscopy for the diagnosis of shoulder pathology increased in the 1980s, in part because of its accuracy, which was far greater than that of clinical examination and

better than the accuracy of other diagnostic modalities of the time. With technologic advances in fiber optics, video output, and arthroscopic instrumentation, the use of arthroscopy to diagnose and treat shoulder problems exponentially increased to include procedures previously used only for open techniques.⁴⁴

Compared with DCAT, arthroscopy is more accurate in the diagnosis of intra-articular lesions associated with a painful shoulder.³⁰ An additional benefit is that arthroscopy can be used to diagnose and treat shoulder problems of the glenohumeral joint and the subacromial region. With increased accuracy of MRI-arthrography in detecting partial cuff tears and labral lesions, diagnostic shoulder arthroscopy has become less common in the absence of clear indications and specific treatment plans. In combination with a detailed history and physical examination, and along with examination under anesthesia, shoulder arthroscopy has been helpful in the diagnosis of chronic instability patterns of the glenohumeral joint.⁴⁴⁻⁴⁷

The indications and usefulness of shoulder arthroscopy in the treatment of common pathologic conditions have continued to increase as the technology improves, and as understanding of the pathophysiology of shoulder problems grows. Shoulder arthroscopy has been used routinely to confirm and treat SLAP lesions, labral tears, partial cuff

tears, refractory adhesive capsulitis, partial biceps tendon tears, and multidirectional instability. Other conditions that are routinely treated arthroscopically include rotator cuff tears, glenohumeral instability, AC joint pathology, loose bodies, sepsis, osteochondritis dissecans, synovitis, chondral lesions, subacromial impingement, and calcific tendinitis.^{7,13,44,47}

Magnetic Resonance Imaging

MRI has been used to diagnose partial-thickness and full-thickness rotator cuff tears, biceps tendon tears, impingement of the rotator cuff, synovitis, articular cartilage damage, and labral pathology associated with glenohumeral instability.⁴⁸⁻⁵⁰ In rheumatoid arthritis, MRI is reported to be more sensitive than plain radiographs in determining soft tissue abnormalities and osseous abnormalities of the glenoid and humeral head.⁵¹

One of the most valuable diagnostic uses of MRI is in rotator cuff pathology. Morrison and Offstein⁵² studied 100 patients with chronic subacromial impingement syndrome using arthrography and MRI. MRI was 100% sensitive but only 88% specific in confirming arthrography-proven rotator cuff tears. Nelson and associates⁵³ studied 21 patients with shoulder pain and found MRI to be more accurate than CT-arthrography or ultrasound in identifying partial-thickness cuff tears. These investigators also reported MRI

to be as accurate as CT-arthrography in the diagnosis of abnormalities of the glenoid labrum.⁵³

Characteristic MRI findings in rotator cuff tears include a hypointense gap within the supraspinatus muscle tendon complex on T1-weighted films, absence of a demonstrable supraspinatus tendon with narrowing of the subacromial space, and an increased signal within the supraspinatus tendon on T2-weighted images.⁵⁴ Seeger and colleagues,⁵⁵ reporting the results of 170 MRI studies, found that T1-weighted images were highly sensitive for identifying abnormalities within the supraspinatus tendon, but T2-weighted images were required to differentiate tendinitis from a small supraspinatus tendon tear. Large full-thickness tears could be identified, however, on T1-weighted and T2-weighted images. Figure 46-12 depicts common shoulder pathology as seen by MRI. MRI is almost as sensitive as and is more specific than scintigraphy in the diagnosis of osteonecrosis and neoplastic lesions around the shoulder.

Electromyography and Nerve Conduction Velocity Studies

EMG and nerve conduction velocity studies can help differentiate shoulder pain from pain of neurogenic origin. They also may be beneficial in determining the localization of neurogenic pain to a particular cervical root, the brachial plexus, or a peripheral nerve.^{56,57}

Figure 46-11 **A**, Normal longitudinal view of rotator cuff by ultrasound shows the humeral head (1), the superior articular surface (2), the rotator cuff (3), the deltoid tendon (4), and tapering of the cuff to its insertion on the greater tuberosity (5). **B**, Transverse view of a normal intact rotator cuff covering the humeral head. **C**, Rotator cuff tear, showing a hypoechoic area (arrow) on a longitudinal view. **D**, Rotator cuff tear, showing hypoechoic area (arrows) on a transverse view.

Injection

Injection of local anesthetics and glucocorticoids is a useful technique for the diagnosis and treatment of shoulder pain.⁵⁸ The physician must have a thorough understanding of the anatomy of the shoulder girdle and a presumptive diagnosis to direct the injection properly. Injection of referred pain areas may be misleading. In a patient with lateral arm pain secondary to deltoid bursal involvement from calcific tendinitis of the supraspinatus tendon, injection should be performed in the subacromial space, rather than in the area of referred pain in the deltoid muscle. It is often better to use a posterior or lateral subacromial approach when injecting a rotator cuff tendinitis in a patient with anterior impingement symptoms because it is easier to enter the subacromial region posteriorly or laterally, and this approach is less traumatic for contracted anterior structures.

The instillation of rapidly acting local anesthetics can be beneficial in determining the source of shoulder pain. Obliteration of pain by injection of a local anesthetic along the bicipital groove can confirm a diagnosis of bicipital tendinitis. The use of local anesthetics is less helpful when the subacromial space is injected because of its extensive communication with the rest of the shoulder girdle, but relief of symptoms by such an injection can exclude pain from conditions such as cervical radiculopathy or entrapment neuropathy.

Potential Diagnostic Tests

Table 46-2 lists reimbursement and charges for various shoulder diagnostic tests based on 2011 Medicare fee schedules and 2011 charges at a single institution. The choice of a specific test depends on its sensitivity, specificity, and cost-benefit analysis. History and physical examination are the most important factors in establishing diagnosis of the painful shoulder. Plain radiographs (three views) should be the first radiographic tests performed. Although not as sensitive as the more sophisticated tests, plain radiographs can identify arthritic change, calcific tendinitis, established osteonecrosis, and most neoplasms.

If intra-articular pathology (e.g., labrum tear, capsular tear, loose body, chondral defect) is suspected, MRI-arthrography is preferable to CT-arthrography. In diagnosing acute rotator cuff tears in a younger patient, ultrasound is the most cost-effective test to confirm a clinical suspicion. In cases of impingement syndrome, MRI is sensitive, but it is difficult to differentiate tendinitis, partial tears, and small complete tears without MRI-arthrography. Orthopedic surgeons prefer MRI-arthrography for verification of labral tears or partial rotator cuff tears. In the case of a suspected full-thickness rotator cuff tear, MRI is preferred to determine the size of the tear, the amount of muscle atrophy and tendon retraction, and the quality of remaining tissue for repair.

Figure 46-12 **A**, Magnetic resonance imaging (MRI) proton density-weighted coronal view shows the supraspinatus tendon as a black band (**A**) that has an increased signal as it nears insertion on the greater tuberosity (**B**). **B**, Similar view in a T2-weighted image shows increased signal as gray (arrow), indicating a partial-thickness tear or tendinitis. **C**, MRI proton density-weighted coronal view shows abrupt end of supraspinatus tendon as it courses right to left (**A**). From **A** to **B** is an area of increased signal followed by a short portion of tendon (**B**) inserting at the greater tuberosity. **D**, Similar view in a T2-weighted image shows increased signal as white (fluid density), indicating fluid in the gap of a complete rotator cuff tear. **E**, MR arthrography shows a normal rotator cuff. **F**, MR arthrography shows a chronic cuff tear with retraction.

INTRINSIC FACTORS CAUSING SHOULDER PAIN

Periarticular Disorders

Shoulder Impingement and Rotator Cuff Tendinopathy

One of the most common nontraumatic causes of shoulder pain is impingement with rotator cuff tendinopathy. In 1972, Neer⁹ described his results of 100 anatomic shoulder dissections and coined the term *impingement syndrome*. Impingement may be defined as the encroachment of the

acromion, coracoacromial ligament, coracoid process, or AC joint on the rotator cuff as it passes beneath them during glenohumeral motion. The function of the posterior rotator cuff is to abduct and externally rotate the humerus. The cuff with the biceps tendon serves as a humeral head depressor to maintain the head centered within the glenoid fossa as the cuff and to use the deltoid to elevate the arm.⁵⁹⁻⁶¹

Controversy continues, however, as to the exact cause of impingement, that is, whether it is a primary, intrinsic, degenerative event within the tendon with superior migration of the head on arm elevation and secondary

Table 46-2 Relative Costs of Shoulder Diagnostic Procedure in 2011

Procedure	Initial Fee (USD)	Technical Fee (USD)	Interpretation Fee (USD)
Medicare B Fee Schedule			
Initial office visit (30 min)	154.00		
Plain radiography (3 views)		36.28	23.09
Arthrography		156.08	34.07
Ultrasonography		74.70	41.62

impingement on the acromion, or purely mechanical attrition of the tendon with primary impingement against the acromion. The mechanical impingement of the rotator cuff may be influenced by variations in the shape and slope of the acromion.^{62,63} The supraspinatus outlet may become narrowed from proliferative spur formation of the acromion or degenerative changes in the AC joint. These changes, along with intrinsic degenerative changes of the rotator cuff, may lead to rotator cuff tear, but the exact pathogenesis remains controversial. Many studies have found a strong correlation between degenerative hypertrophic spur formation, with its resulting narrowing of the supraspinatus outlet, and the presence of full-thickness cuff tears,^{9,19,64-71} but clinical studies have failed to confirm whether hypertrophic changes in the coracoacromial arch are caused by the cuff lesions, or whether these changes themselves cause the lesions.

Neer⁹ developed a staging system for description of impingement lesions of the shoulder. A stage I lesion involves edema and hemorrhage of the rotator cuff and is typically found in individuals younger than 25 years who are active in overhead athletics. The condition usually responds to conservative treatment that includes rest, anti-inflammatory medication, and physical therapy. Stage II lesions usually occur in the 30s or 40s and represent the biologic response of fibrosis and thickening of the tendon after repeated episodes of mechanical impingement over time. Lesions are treated conservatively, as in stage I, but attacks may recur. If symptoms persist despite adequate conservative management for longer than 6 to 12 months, surgical intervention is warranted. Stage III lesions involve rotator cuff tears, biceps tendon rupture, and bone changes, and they rarely occur before age 40. Patients may present with pain, weakness, or supraspinatus atrophy, depending on the chronicity of the tear. Surgical treatment depends on the patient's age, loss of function, weakness, and pain.

Patients usually present to the clinician with a complaint of pain that has failed to resolve after a variable period. Pain can be sudden and incapacitating in cases of traumatic cuff tears, or more commonly may manifest as a dull ache in cases of chronic impingement. Pain usually is located over the anterior and lateral aspects of the shoulder and may radiate into the lateral deltoid. It may worsen with sleeping

on the affected extremity and is exacerbated by overhead activity. Tenderness on palpation may be elicited over the greater tuberosity and the long head of the biceps within the bicipital groove, indicating an associated biceps tendinitis. In cases with concomitant degenerative changes in the AC joint, tenderness may be noted on palpation over the AC joint, as an offending osteophyte impinges on the rotator cuff beneath.

The impingement sign as described by Neer⁹ (Figure 46-13) is useful in the diagnosis of rotator cuff tendinopathy. The patient often describes a catch as the arm is brought into the overhead position. The patient may be observed to raise the arm by abduction and external rotation to clear the greater tuberosity of the acromion, bypassing the painful area. A typical painful arc usually occurs between 70 degrees and 110 degrees of abduction. Neer⁹ also described an impingement test that involves injection of lidocaine into the subacromial bursa. Relief of pain is a positive impingement test result and usually indicates rotator cuff origin of the shoulder pain.

Figure 46-13 The impingement sign is elicited by forced forward elevation of the arm. Pain results as the greater tuberosity impinges on the acromion. The examiner's hand prevents scapular rotation. This maneuver may be positive in other periarticular disorders. (From Neer CS II: Impingement lesions, *Clin Orthop Relat Res* [173]:70, 1983.)

Radiographs in the early stages of cuff tendinopathy may be normal or may reveal a hooked acromion. As the disease progresses, sclerosis, cyst formation, and sclerosis of the anterior third of the acromion and the greater tuberosity may be observed. An anterior acromial traction spur may appear on the undersurface of the acromion lateral to the AC joint and represents contracture of the coracoacromial ligament. Late radiographic findings include narrowing of the acromiohumeral gap, superior subluxation of the humeral head in relation to the glenoid, and erosive changes in the anterior acromion.⁷¹ Arthrography, MRI, and ultrasound may be helpful in diagnosing a full-thickness tear of the rotator cuff in association with stage III disease. In some cases of chronic large rotator cuff tears, proximal migration of the humeral head leads to a pattern of degenerative arthritis termed *cuff-tear arthropathy*.

The choice of treatment and frequently its result are functions of the stage of the impingement and the response to pain. In stage I disease, in which little mechanical impingement occurs, most patients respond to rest. It is important to avoid immobilizing the shoulder for any period because contraction of the shoulder capsule and periarticular structures can produce an adhesive capsulitis. After a period of rest, a progressive program of stretching and strengthening exercises generally restores the shoulder to normal function. Use of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) may shorten the symptomatic period. Modalities such as ultrasound, neuroprobe, and transcutaneous electrical nerve stimulation generally are not helpful. Patients with stage I or II disease may have a dramatic response to local injection of glucocorticosteroids and local anesthetic agents. For stage II disease in which fibrosis and thickening occur anteriorly, it is frequently better to inject through a posterior approach. We prefer a combination of 3 mL of 1% lidocaine (Xylocaine), 3 mL of 0.5% bupivacaine, and 20 mg of triamcinolone. This injection combines a short-acting anesthetic to help confirm the diagnosis, a longer-acting anesthetic for analgesic purposes, and a steroid preparation in a depot form.

An integrated program of occupational and physical therapy often precludes the need for surgery in patients with stage II disease. Job modification for individuals with impingement syndrome caused by overuse may alleviate symptoms. Businesses are becoming increasingly aware of the cost savings associated with proper job ergonomics.^{72,73}

The initial rehabilitation in stage II impingement consists of cessation of repetitive overhead activity. Ice, NSAIDs, and local injections also may be beneficial. Initial physical therapy includes passive, active-assisted, and active range of motion combined with stretching and mobilization exercises to prevent contracture. As pain and inflammation subside, isometric or isotonic exercises are used to strengthen the rotator cuff musculature. Isokinetic training at variable speeds and in variable positions is instituted before the patient is returned to full activity. For patients with a job-related injury, it is crucial to review and modify job mechanics to prevent recurrent episodes that can cause further disability and may precipitate the need for surgery.⁷²

Neer¹⁹ suggested that a patient with refractory stage II disease may respond to division of the coracoacromial ligament and bursectomy of the subacromial bursa. Open anterior acromioplasty as described by Neer has become accepted

as the procedure of choice for stage II and III impingement lesions, with many investigators reporting high success rates in treating impingement syndrome and rotator cuff tears.⁷⁴⁻⁷⁷ Reported results show good and excellent relief of symptoms in 71% to 87% of patients treated by the open surgical procedure.⁷⁸⁻⁸¹

In 1985, Ellman⁴⁵ described the technique of arthroscopic subacromial decompression. His initial results⁴⁶ and the results of others are comparable with those of open surgical techniques.^{47,82} Arthroscopic subacromial decompression has become a widely accepted treatment for refractory stage II and III impingement lesions. The procedure can be done as outpatient surgery, and because no deltoid is detached, as with the open technique, the procedure facilitates rehabilitation and increases overall recovery rates.

Calcific Tendinitis

Calcific tendinitis is a painful condition around the rotator cuff that is associated with deposition of calcium salts, primarily hydroxyapatite.⁸³⁻⁸⁵ The cause of calcific tendinitis is unknown. The commonly accepted cause is degeneration of the tendon, which leads to calcification through a dystrophic process.⁸⁵ A common clinicopathologic correlation is seen in three distinct phases of the disease process: the precalcific or formative phase, which can be relatively painless; the calcific phase, which tends to be quiescent and may last months to years; and the resorptive or postcalcific phase, which tends to be painful, as calcium crystals are resorbed.⁸³ Although it is more common in the right shoulder, at least a 6% incidence of bilaterality has been reported. Patients with bilateral shoulder involvement often have the syndrome of calcific periarthritis, in which calcium hydroxyapatite crystals are found at multiple sites.⁸⁶ Patients usually present with impingement-type pain in the affected shoulder during overhead activity. The pain may seem to be out of proportion to any objective physical findings. The patient may describe difficulty sleeping on the shoulder and trouble falling asleep. Symptoms may last a few weeks or a few months.

The incidence of calcific tendinitis varies in the literature among asymptomatic individuals from 2.7% to 20%. Most calcification occurs in the supraspinatus tendon, and 57% to 76.7% of patients are women. The average age of patients is 40 to 50 years.^{83,87}

Codman¹ pointed out the localization of calcification within the tendon of the supraspinatus. He provided a detailed description of the symptoms and the natural history of this condition. In describing the phases of pain, spasm, limitation of motion, and atrophy, he noted the lack of correlation between symptoms and the size of the calcific deposit. According to Codman, the natural history includes degeneration of the supraspinatus tendon, calcification, and eventual rupture into the subacromial bursa. During the latter phase, pain and decreased motion can lead to adhesive capsulitis (see Figure 46-8).

Several factors may affect localization of calcium within the supraspinatus. Many patients have an early stage of impingement, which compresses the supraspinatus tendon on the anterior portion of the acromion.^{9,19} This longstanding impingement may lead to local degeneration of tendon fibers. In patients without impingement,

localization of calcium within the supraspinatus may be related to the blood supply of the rotator cuff, which normally is derived from an anastomotic network of vessels from the greater tuberosity or from the bellies of the short rotator muscles.⁸⁴ The watershed of these sources is just medial to the tendinous attachment of the supraspinatus.⁸⁸ Rathburn and Macnab⁸⁹ referred to this watershed as the critical zone and pointed out that during abduction this area was rendered ischemic.

Treatment of calcific tendinitis depends on the clinical presentation and the presence of associated impingement. Patients can have an acute inflammatory reaction that may resemble gout. The acute inflammation can be treated with local glucocorticoid injection, NSAIDs, or both. Ultrasound may be beneficial. If impingement is associated, treatment depends on the stage at presentation. The radiographic appearance of the calcification can direct and perhaps predict the response to therapy. In the resorptive state, deposits appear floccular, suggesting that the process is in the phase of repair, and that a conservative program is indicated.

Patients with discrete calcification and perhaps associated adhesive capsulitis (see Figure 46-8) may be at a stable phase, in which calcium produces a mechanical block and is unlikely to be resorbed. For these patients, mechanical removal of calcific deposits and correction of associated pathologic lesions may be necessary.⁹⁰⁻⁹² Percutaneous disruption of calcified areas may be performed using a needle directed by fluoroscopy. This technique allows lavage and injection, but does not treat associated impingement. Subacromial arthroscopy allows mechanical débridement of calcific deposits under direct visualization. This technique can be combined with arthroscopic removal of the inflamed bursa and decompression of associated impingement. Improved results have been noted with complete removal of calcific deposits.⁹³ In many cases of refractory calcific tendinitis associated with impingement, open or arthroscopic acromioplasty, subacromial bursectomy, and decompression are indicated.

Rotator Cuff Tear

Pathophysiology

Spontaneous tear of the rotator cuff in an otherwise normal individual is rare.¹⁹ It can occur in patients with rheumatoid arthritis or systemic lupus erythematosus as part of the pathologic process with invasion from underlying pannus. Metabolic conditions such as renal osteodystrophy and agents such as glucocorticoids occasionally are associated with cuff tears. Most patients report a traumatic episode, such as falling on an outstretched arm or lifting a heavy object. The usual presenting symptoms are pain and weakness of abduction and external rotation. Crepitus and even a palpable defect may be associated. Long-standing tears generally are associated with atrophy of the supraspinatus and infraspinatus muscles. It may be difficult to differentiate a painful tendinitis from a partial-thickness or a small full-thickness cuff tear.

Controversy continues about the exact cause of cuff tendinopathy.^{88,92,94,95} Most likely, the pathophysiology involves a combination of factors, including decreased vascularity

and cellularity of the tendon, along with changes in the collagen fibers of the tendon that occur with aging.

Loss of motion with subsequent capsular tightness, particularly in the posterior capsule, may lead to cephalad migration of the humeral head, with subsequent impingement of the cuff under the coracoacromial arch.⁹⁶ Rehabilitation exercises stress regaining a normal range of motion. To achieve full, painless motion, the normal relationship of glenohumeral to scapulothoracic motion must be achieved.^{16,17,97}

Diagnosis

History. Patients with nontraumatic tears of the rotator cuff report symptoms of chronic impingement. Loss of motion and a feeling of stiffness are often noted with extremes of motion, along with difficulty during activities of daily living, such as combing the hair, hooking a bra strap, putting on a shirt or coat, and reaching into the back pocket. In chronic cases of cuff tendinopathy, loss of motion usually occurs. Limitation of internal rotation occurs initially, is caused by posterior capsular contracture, and is often associated with posterior shoulder pain with adduction of the ipsilateral shoulder. Further shoulder impingement occurs with forward flexion because of superior migration of the humeral head against the anterior inferior acromion. This upward translation is analogous to the action of a yo-yo climbing on a string.^{96,98} Over time, loss of forward flexion, abduction, and external rotation occurs with passive and active motion of the shoulder.

Imaging. In acute cases, a history of trauma, such as a fall onto the affected shoulder, may be reported. In cases involving an anterior shoulder dislocation with subsequent profound weakness of the rotator cuff, a large cuff tear or a greater tuberosity avulsion should be suspected, in addition to axillary nerve palsy. In younger patients, traumatic failure of the cuff under tensile overload may result in cuff failure caused by forced adduction of the affected shoulder or active abduction against resistance, and this may occur with traumatic dislocation. Repetitive tensile overload also can result in partial rotator cuff tears in an overhead athlete.

Plain radiographs are used in initial evaluation of impingement-type shoulder pain with cuff tendinopathy. An impingement series should be ordered, including an anteroposterior radiograph with a 30-degree cephalic tilt (Rockwood view), which can reveal osteophytes of the anterior os acromion and AC joint; a scapular Y view with a 10-degree cephalic tilt (supraspinatus outlet view), which can evaluate the type of acromion and reveal anterior and AC osteophytes; and an axillary view, which can evaluate the acromion for possible os acromionale. Calcific deposits within the rotator cuff tendon can be viewed best with rotational anteroposterior radiographs. Cuff arthropathy should be suspected if the acromial-humeral distance is less than 7 mm, or with the presence of cyst formation within the greater tuberosity, humeral head osteopenia, sclerosis around the greater tuberosity, or humeral head collapse. In advanced stages of cuff arthropathy, complete loss of glenohumeral joint space may be seen with superior migration and abutment of the humeral head against the undersurface of the acromion.⁵⁹

In the past, shoulder arthrography was considered the “gold standard” for diagnosing full-thickness and partial-thickness rotator cuff tears, with greater than 90% sensitivity and specificity.^{33,99} Currently, arthrography with CT or MRI is routinely used to diagnose rotator cuff pathology, including full-thickness and partial-thickness tears.

Ultrasonography has been accurate in the diagnosis of full-thickness rotator cuff tears.^{39,100-103} Ultrasonography offers the advantages of being inexpensive and noninvasive, but disadvantages include unproven effectiveness in determining subacromial impingement, capsular and labral abnormalities, and partial cuff tears. The procedure and its results are technician dependent. Ultrasonography may have a useful role in determining the postoperative integrity of the cuff repair.³⁸

MRI has been invaluable in evaluating rotator cuff tears. Sensitivity and specificity of MRI for diagnosing full-thickness cuff tears are 100% and 95%.¹⁰⁴ Through the use of gadolinium or saline, partial tears that are otherwise difficult to detect with conventional imaging can be detected.

Diagnosing cuff tears with MRI usually is based on discontinuity of the tendon on T1-weighted images and consistency with fluid signal on T2-weighted images. Ancillary findings include fluid in the subacromial space on T2-weighted images, loss of the subacromial fat plane on T1-weighted images, and proliferative spur formation of the acromion or AC joint. Large, chronic cuff tears also may be associated with cephalad migration of the humeral head and fatty atrophy of the spinatus muscle. Periarticular soft tissues, including the capsulolabral complex and the biceps tendon, as well as the rotator cuff can be thoroughly examined. The degree of tear and tendon retraction and evidence of muscle atrophy can be evaluated, all of which are crucial in preoperative planning for possible cuff repair.

Treatment

Nonsurgical Treatment. Codman and Akerson⁶⁴ recommended early operative repair for acute full-thickness rotator cuff tears and reported the first documented repair in 1911. McLaughlin⁶⁶ recommended early repair in cases of grossly displaced tuberosity fractures or massive tears. Several other clinical studies have supported the concept that a full-thickness tear does not preclude good shoulder function. DePalma¹⁰⁵ reported that 90% of patients with rotator cuff tears responded to conservative measures, such as rest, analgesics, anti-inflammatory agents, and physiotherapy.

The reported percentage of patients responding to nonsurgical treatment in the literature varies from 33% to 90%.^{3,18,106} Conservative treatment includes pain control with NSAIDs, ultrasound, heat before shoulder stretching and exercise, and ice after overhead activity. Deep massage therapy is employed to reduce trigger point tenderness within the trapezius, levator scapulae, and periscapular muscles. Patients on long-term anti-inflammatory medications are monitored periodically for evidence of gastrointestinal bleeding and for hepatic or renal toxicity. Opiate-based drugs are used only in the acute setting, such as after a fall, or in the perioperative period.

Steroid and local anesthetic injections are used when the patient has significant pain that prohibits rehabilitation.

Injections may be repeated once every 3 months if needed; injection into the cuff tendon is to be avoided. If the patient fails to improve after 3 months of conservative treatment, or does not continue to improve after three sequential injections, surgical options should be discussed.

The mainstay of conservative therapy is exercise. Rehabilitation stresses pain relief with exercises aimed at restoring shoulder motion and strengthening remaining cuff muscles, deltoid, and scapular stabilizers. Therapy can be divided into three phases. The goals of the initial phase of therapy are to relieve pain and restore shoulder motion. Motion therapy includes pendulum exercises, passive motion with use of a wand with assistance of the uninvolved shoulder, an overhead pulley system, and posterior capsular stretching. The arc of motion is gradually increased and is guided by the patient's discomfort to avoid painful impingement arcs.

The second phase of therapy is entered after the patient has return of motion and little discomfort with overhead activity. Emphasis is placed on strengthening the remaining rotator cuff musculature and deltoid and periscapular muscles. Strengthening with elastic surgical tubing provides variable degrees of resistance, depending on the size of the tubing. Initial strengthening is performed out of the impingement arc (70 to 120 degrees of shoulder flexion). The goal of this phase is to strengthen the shoulder to prevent dynamic proximal humeral migration with impingement during active shoulder elevation.^{59,61} Normal shoulder kinematics relies on combined and synchronous glenohumeral flexion and scapular rotation.^{60,92} In addition to strengthening the cuff and deltoid, the scapular rotators, including the trapezius and the serratus anterior muscles, are emphasized.¹⁰⁷

After the patient has successfully completed phase two of the rehabilitation program with minimal symptoms and good shoulder function, the final phase is entered. Phase three is characterized by a gradual return to normal overhead activities, including work and sporting activities. This part of the rehabilitation program should be tailored to the individual patient's needs and the demands placed on the shoulder.

Surgical Treatment. A Cochrane review of the effectiveness of surgery for rotator cuff disease failed to reach any firm conclusions about the effectiveness or safety of rotator cuff surgery.¹⁰⁸

Severity and duration of pain are the primary indications for surgical intervention in a rotator cuff tear. Other factors important in surgical decision making include shoulder dominance, activity level, physiologic age, acuteness of the tear, degree of tear, loss of function, amount of tendon retraction, and fatty atrophy of the remaining cuff musculature.

A systematic review of indications for rotator cuff surgery found that earlier surgical intervention may be needed for patients with cuff tears with weakness and significant functional disability. In addition, older chronologic age did not portend a worse outcome; however, pending workman's compensation claims, it did negatively affect treatment results.¹⁰⁹

Acute Tears. Acute tears of the rotator cuff can be treated with conservative measures of periscapular and cuff strengthening along with capsular stretching to restore

motion. Early surgical intervention should be considered in a young patient, especially an overhead athlete. Conservative shoulder rehabilitation should be maintained for 3 to 6 months before a decision is made regarding surgery for an older sedentary patient, in whom functional results without surgery may be acceptable. Many older patients may function well with chronic cuff tears, but they may become debilitated if an acute tear is superimposed on chronic changes. Surgical intervention may be required in these cases to return the patient to baseline function by repairing the acute tear and attempting to repair the chronic tear if possible.

Chronic Tears. For elderly patients whose pain and weakness do not create a functional problem, a conservative program is preferable for chronic tears. Pain unresponsive to conservative management is the main indication for surgery in an older patient with a chronic rotator cuff tear. In these cases, surgery should be considered on an individual basis after at least 3 months of conservative treatment, including subacromial steroid injection. If the cuff tear is massive and irreparable, débridement and subacromial decompression may provide good pain relief without extensive surgery and prolonged immobilization.^{46,82,110-114} In a younger patient with a chronic tear and weakness, surgery to repair the cuff may be indicated to improve strength and prevent further extension of the tear.¹¹²

In cases of rotator cuff arthropathy with glenohumeral joint degeneration, a reverse total shoulder replacement may be indicated. This type of total shoulder replacement reverses the normal relationship between scapular and humeral components, moving the center of rotation medially and distally to increase the lever arm length of the deltoid muscle. The deltoid compensates for the deficient rotator cuff, allowing as near-normal function as possible (Figure 46-14). A recent publication also suggested reverse

total shoulder arthroplasty for the treatment of irreparable rotator cuff tear with disability and no glenohumeral arthritis.¹¹⁵

Bicipital Tendinitis and Rupture

The long head of the biceps passes through the bicipital groove, crosses over the head of the humeral, and inserts on the superior rim of the glenoid (see Figure 46-1A).¹¹⁶ The biceps tendon aids in flexion of the forearm, supination of the pronated forearm if the elbow is flexed, and forward elevation of the shoulder.³ Bicipital tendinitis, subluxation or dislocation of the biceps tendon within the bicipital groove, and rupture of the long head of the biceps generally are associated with anterior shoulder pain.

Bicipital tendinitis is sometimes an associated feature of a rotator cuff tear. The rotator cuff tear compromises centering of the humeral head on the glenoid. This compromise results in increased mechanical loading of the long head of the biceps, which initiates a hypertrophic tendinitis.¹¹⁷

Dislocation of the long head of the biceps usually is combined with a lesion of the subscapularis tendon.¹² Isolated rupture of the long head of the biceps tendon is rare when the rotator cuff is intact. Rupture of the long head of the biceps is common, however, when a coexisting rotator cuff tear is present.¹¹⁸ The effects of rotator cuff tear and concomitant biceps tendon rupture on strength can be substantial.¹²

Early phases of bicipital tendinitis are associated with hypervascularity, edema of the tendon, and tenosynovitis.¹¹⁹ Persistence of this process leads to adhesions between the tendon and its sheath, along with impairment of the normal gliding mechanism in the groove. Stretching of the adhesions may be associated with chronic bicipital tendinitis.¹²⁰ The diagnosis of bicipital tendinitis is based on localization of tenderness. It is often confused with impingement symptoms and is frequently seen with an impingement syndrome.²⁴ Isolated bicipital tendinitis can be differentiated by the fact that the tender area migrates with the bicipital groove as the arm is abducted and externally rotated. Many eponyms are associated with tests to identify bicipital tendinitis.³ Yergason's supination sign refers to pain in the bicipital groove when the examiner resists supination of the pronated forearm with the elbow at 90 degrees. Ludington's sign refers to pain in the bicipital groove when the patient interlocks the fingers on top of the head and actively abducts the arms.

Biceps tendon rupture can occur in some patients who report no history of shoulder pain. Patients often complain of an acute onset of pain and ecchymosis around the anterior shoulder and sagging of the biceps muscle belly. In these cases, a concomitant rotator cuff injury should be excluded by clinical examination. More often, the biceps tendon rupture is preceded by painful shoulder symptoms that often improve or disappear after the rupture.^{120,121}

Treatment generally is conservative and consists of rest, analgesics, NSAIDs, and local injection of glucocorticoids. The use of ultrasound and a neuroprobe is more beneficial in this condition than in isolated rotator cuff tendinitis. Patients with refractory bicipital tendinitis and recurrent symptoms of subluxation are treated by arthroscopic biceps tenodesis or open tenodesis, that is, opening the bicipital

Figure 46-14 Reverse total shoulder replacement in a 72-year-old man who had severe cuff arthropathy.

groove and resecting the proximal portion of the tendon with tenodesis of the distal portion into the groove or beneath the pectoralis tendon.

Acromioclavicular Disorders

The AC joint is a common source of shoulder pain. Acute causes of AC joint pain are often related to direct trauma of the affected shoulder that may result in a distal clavicle injury with an intra-articular chondral fracture, or in AC joint instability from ligamentous disruption.¹²²

Post-traumatic distal clavicle osteolysis, with resorption of the distal clavicle, may ensue 4 weeks after a shoulder injury, leading to AC joint pain.^{123,124} Osteolysis may be caused by microfracture of the subchondral bone and subsequent attempts at repair.¹²⁵ Other authors believe the cause to be an autonomic nerve dysfunction affecting the blood supply to the clavicle. The increased blood supply leads to resorption of bone from the distal clavicle.^{123,126} More commonly, chronic osteolysis results from repetitive microtrauma to the AC joint from activities such as weight lifting, gymnastics, and swimming.^{125,127,128}

The underlying pathophysiology is believed to be an inflammatory process caused by stress fracture of the subchondral bone with hyperemic resorption of the distal clavicle.^{125,129} Other causes of osteolysis include rheumatoid arthritis, hyperparathyroidism, and sarcoidosis, which should be considered in the differential diagnosis, especially in bilateral cases.^{123,124} Patients with atraumatic osteolysis of the distal clavicle should be forewarned that bilateral involvement may occur; an incidence of 70% was reported for one long-term follow-up.¹³⁰ Other chronic causes of AC pain include idiopathic, intra-articular disk pathology, post-traumatic degenerative arthrosis from joint incongruity, primary degenerative arthrosis, and rheumatoid arthritis.

Evaluation should always include a detailed history, physical examination, and radiographic evaluation. A history of trauma to the AC joint from a direct fall or blow to the ipsilateral shoulder may be reported. Less commonly, the AC joint may have been injured indirectly, as during a fall on the outstretched arm with forces transmitted through the arm to the AC joint.^{122,131} Patients with osteolysis of the distal clavicle sometimes give a history of acute trauma, although the more common cause is repetitive microtrauma to the AC joint caused by activities such as weight lifting or gymnastics.^{123,124,127,128}

Patients frequently complain of pain over the AC joint when adducting the ipsilateral shoulder, such as during a golf swing or when buckling a seat belt. Often, pain occurs when sleeping on the affected shoulder. Athletes may experience AC joint pain on bench pressing, push-ups, and dips.^{130,132,133} Pain and weakness of the affected shoulder also may be experienced with forward flexion and adduction of the arm.¹²³

On physical examination, a visible step-off may be observed between the medial acromion and the distal clavicle, indicating a probable AC separation. Pain usually can be elicited on direct palpation of the AC joint and is made worse by a cross-arm adduction maneuver. This test is performed by internally rotating the arm, which is maximally adducted across the chest, and is considered positive if pain is produced in the AC joint (see [Figure 46-3D](#)). Pain also

may be elicited by moving the arm from a horizontally abducted position to the extended position and on maximal internal rotation of the shoulder.^{132,134} These tests cause rotation and compression of the AC joint and are sensitive but less specific. They also may be positive with other disorders of the shoulder, such as posterior capsular stiffness.¹³⁵

Frequently, AC joint pain coexists with subacromial impingement and rotator cuff pathology. In these cases, impingement signs are positive, and rotator cuff weakness may be present. Otherwise, no muscle weakness should be detectable on manual resistance testing, and no evidence of muscle atrophy should be found.^{130,135,136} The AC joint and the subacromial space may have to be injected on separate occasions to determine the true source of the symptoms. Some physicians have noticed an association of AC joint symptoms with shoulder instability.¹³⁰ Glenohumeral motion can vary, depending on chronicity and isolation of the problem to the AC joint. In isolated cases, some loss of internal rotation of the affected shoulder may be caused by pain.

Radiographs should include anteroposterior views of the shoulder in the scapular plane in neutral, internal, and external rotation; a transcapular Y view; an axillary view; and a 15-degree cephalic tilt view of the AC joint at 50% penetrance, as described by Zanca (see [Figure 46-4](#)).²³ Stress views may be obtained by strapping 5 to 10 lb of weight to the forearms and determining AC separation. Comparing the coracoclavicular distance of both shoulders also may be helpful. When clinically indicated, cervical spine radiographs should be obtained to exclude cervical spondylosis.

Radiographic evaluation may reveal AC joint arthrosis with microcystic changes in the subchondral bone, sclerosis, osteophytic lipping, and joint space narrowing.¹³⁷ In cases of osteolysis, radiographs may reveal loss of subchondral bone detail with microcystic appearances in the subchondral region of the distal clavicle and osteopenia of the lateral one-third of the clavicle.^{124,125,127,128} In late stages of osteolysis, resorption of the distal end of the clavicle results in marked widening of the AC joint and sometimes complete resorption of the distal clavicle. AC separation may be evident with widening of the coracoclavicular distance and post-traumatic ossification of the coracoclavicular ligaments.

AC symptoms do not always correlate with the radiographic appearance of the joint. DePalma¹³⁸ found AC joint degeneration to be an age-related process, with symptoms not always correlating with radiographic findings of AC joint arthrosis.²³ AC joint pain may occur despite normal radiographs.¹³⁹

A technetium 99m phosphate bone scan may assist in the diagnosis, revealing increased uptake in the distal clavicle and the medial acromion.¹²⁵ In cases of atraumatic osteolysis of the distal clavicle, increased uptake may be isolated to the distal clavicle, but in approximately 50% of cases, scintigraphic activity of the adjacent medial acromion is increased.¹³⁰ The bone scan may reveal pathologic changes in the AC joint when plain radiographs appear normal.

In selected cases, MRI can be valuable in determining a diagnosis and evaluating the glenohumeral and subacromial regions for coexisting pathology ([Figure 46-15](#)). AC joint involvement may reveal increased fluid with synovitis, soft

tissue enlargement, and periarticular ossifications with encroachment on underlying bursal and cuff tissue.

Patients with AC joint pain usually respond well to non-operative treatment; however, complete relief of symptoms may require an extended period. Conservative therapy includes heat, NSAIDs, steroid injections, shoulder rehabilitation, and avoidance of painful positions and activities. Steroid injections are repeated at 3-month intervals if painful conditions persist.

Open resection of the distal clavicle for chronic AC joint pain was initially reported by Gurd¹⁴⁰ and by Mumford,¹⁴¹ both with good results. Since that time, other surgeons have reported similar good results with open resection, but significant morbidity, such as disruption of the deltotrapezial fascia and anterior deltoid rupture, can occur.^{123,124,137,139,142} Arthroscopic resection of the distal

clavicle has been described with results similar to open resection.^{13,129,134-136,143-146}

Glenohumeral Disorders

The various arthritides that affect the shoulder joint are discussed in detail in other chapters. They are presented here to address aspects that are unique to the glenohumeral joint. The usual presentation of intra-articular disorders consists of pain with motion and symptoms of internal derangement, such as locking and clicking. Pain is generalized throughout the shoulder girdle and sometimes is referred to the neck, back, and upper arm. The usual response to pain includes decreased glenohumeral motion and substitution with increased scapulothoracic mobility. Patients with adequate elbow and scapulothoracic motion require little glenohumeral motion for activities of daily living; patients with glenohumeral arthrodesis can achieve adequate function.^{147,148} The response to pain consists of diminution of motion and secondary soft tissue contractures with muscle atrophy. With increasing weakness and involvement of adjacent joints, pain, limitation of motion, and weakness can cause a substantial functional deficit.

Inflammatory Arthritis

Although the most common inflammatory arthritis involving the shoulder joint is rheumatoid arthritis (RA), other systemic disorders, such as systemic lupus erythematosus, psoriatic arthritis, ankylosing spondylitis, reactive arthritis, and scleroderma, may cause glenohumeral degeneration. Motion is limited by splinting of the joint with secondary soft tissue contractures, or by primary soft tissue involvement with scarring or rupture. Plain radiographs confirm glenohumeral involvement (Figure 46-16A). Narrowing of the glenohumeral joint space may occur, with erosion and cyst formation and without significant sclerosis or osteophytes. As the disease progresses, superior and posterior erosion of the glenoid with proximal subluxation of the humeral head may occur. Eventually, secondary degenerative changes and even osteonecrosis of the humeral head may occur.

Figure 46-16 Plain radiographs. **A**, Rheumatoid arthritis with loss of joint space, cyst formation, glenohumeral erosion, and early proximal subluxation of the humerus, indicating a rotator cuff tear. **B**, Osteoarthritis with narrowing of the glenohumeral joint space, sclerosis, and osteophyte formation. Notice the preservation of the subacromial space, suggesting an intact rotator cuff.

Treatment is initially conservative and is directed toward controlling pain, inducing a systemic remission, and maintaining joint motion through physical therapy. The use of intra-articular glucocorticoids may be beneficial in controlling local synovitis. In rheumatoid arthritis, the involvement of periarticular structures with subacromial bursitis and rupture of the rotator cuff magnifies the functional deficit. When synovial cartilage interactions produce significant symptoms and radiographic changes that cannot be controlled by conventional therapy, glenohumeral resurfacing should be considered.

When following an RA patient with shoulder involvement, the rheumatologist should assess range of motion carefully and should obtain periodic radiographs. Patients with progressive loss of motion or radiographic destruction should be referred for evaluation for possible surgical treatment. The treatment of choice is an unconstrained total shoulder arthroplasty.^{149,150} Total shoulder arthroplasty is best performed in patients with rheumatoid arthritis before end-stage bony erosion and soft tissue contractions have occurred.^{151,152} Acute inflammatory arthritis of the glenohumeral joint may be associated with gout, pseudogout, hydroxyapatite deposition of renal osteodystrophy, and recurrent hemophilic hemarthrosis.

Osteoarthritis

Osteoarthritis of the glenohumeral joint is less common than that in the hip, its counterpart in the lower extremity; this condition is caused by non-weight-bearing characteristics of the shoulder joint and the distribution of forces throughout the shoulder girdle. Osteoarthritis is divided into conditions associated with high unit loading of articular cartilage and conditions in which an intrinsic abnormality within the cartilage causes abnormal wear at normal loads. Because the shoulder is normally a non-weight-bearing joint and is not usually susceptible to repeated high loading, the presence of osteoarthritis of the glenohumeral joint should alert the physician to consider other factors. Has the patient engaged in unusual activities, such as boxing, heavy construction, or long-term use of a pneumatic hammer? Has some disorder, such as epiphyseal dysplasia, created joint incongruity with high unit loading of the articular cartilage? Is this a neuropathic process caused by diabetes, syringomyelia, or leprosy? Have associated hemochromatosis, hemophilia, or gout altered the ability of articular cartilage to withstand normal loading? Is unrecognized chronic dislocation responsible?

Pain is the usual presentation, but generally it is not as acute or it may be associated with the spasm seen in inflammatory conditions. Plain radiographs show narrowing of the glenohumeral joint, osteophyte formation, sclerosis, and some cyst formation (Figure 46-16B). Because the rotator cuff usually is intact, less bone erosion of the glenoid and proximal subluxation of the humerus is noted. Patients with osteoarthritis of the glenohumeral joint frequently do well with functional adjustments and conservative therapy. Analgesics and NSAIDs may provide symptomatic relief. The use of glucocorticoid injections is less beneficial, unless evidence of synovitis is observed. Patients with severe involvement who fail to respond are best treated by shoulder arthroplasty.¹⁴⁹⁻¹⁵²

Osteonecrosis

Osteonecrosis of the shoulder refers to necrosis of the humeral head seen in association with a variety of conditions. Symptoms are due to synovitis and joint incongruity resulting from resorption, repair, and remodeling. Pathogenesis and various causes are discussed in Chapter 103.

The most common cause of osteonecrosis of the shoulder is avascularity resulting from a fracture through the anatomic neck of the humerus.¹⁵³ Fracture through this area disrupts intramedullary and capsular blood supplies to the humeral head.¹⁵⁴ Another common cause of osteonecrosis of the shoulder is steroid therapy provided in conjunction with organ transplantation, systemic lupus erythematosus, or asthma. Other conditions associated with osteonecrosis of the humeral head include hemoglobinopathies, pancreatitis, and hyperbarism.

Early diagnosis is difficult because the presence of symptoms is often delayed. Bone scans may be helpful in early cases, before radiographic changes are evident. MRI is highly sensitive and is more specific than scintigraphy. Plain radiographs show progressive phases of necrosis and repair (as discussed in Chapter 103). In early stages, the films may be normal or may show osteopenia or bone sclerosis. A crescent sign representing subchondral fracture or demarcation of the necrotic segment appears during the reparative process. Patients who fail to remodel show collapse of the humeral head with secondary degenerative changes. A considerable discrepancy is often noted between symptoms and radiographic involvement. Patients with extensive bone changes may be asymptomatic. Treatment should be directed by the patient's symptoms rather than by the radiographs and is similar to that provided for osteoarthritis. Arthroscopy occasionally is helpful by removing loose chondral fragments and debriding chondral incongruities.¹⁵⁵ Patients with severe symptoms that cannot be controlled by conservative means are best treated with unconstrained shoulder arthroplasty, hemiarthroplasty, or resurfacing arthroplasty.¹⁴⁹

Cuff-Tear Arthropathy

In 1873, Adams described the pathologic changes that characterize rheumatoid arthritis of the shoulder and a condition that has since that time been referred to as *Milwaukee shoulder* or *cuff-tear arthropathy*.¹⁵⁶ McCarty called the condition Milwaukee shoulder and reported that factors predisposing to this syndrome included deposition of calcium pyrophosphate dihydrate crystals, direct trauma, chronic joint overuse, chronic renal failure, and denervation.¹⁵⁷ Patients with Milwaukee shoulder have elevated levels of synovial fluid 5-nucleotidase activity and elevated levels of synovial fluid inorganic pyrophosphate and nucleotide pyrophosphohydrolase activity.¹⁵⁸

Neer and colleagues¹⁵⁹ reported a similar condition in which untreated massive tears of the rotator cuff with proximal migration of the humeral head are associated with erosion of the humeral head. Erosion of the humeral head differs from that seen in other arthritides and is presumed to be caused by a combination of mechanical and nutritional factors acting on the superior glenohumeral cartilage.

Patients with cuff-tear arthropathy present a difficult therapeutic problem because bone erosion and disruption of the cuff jeopardize the functional result from an unconstrained prosthesis.¹⁵¹ Hemiarthroplasty or a reverse total shoulder arthroplasty may be indicated.^{160,161} The major challenge in treating cuff-tear arthropathy is to determine which patients with massive rotator cuff tears will proceed to the syndrome of cuff-tear arthropathy. Patients with massive rotator cuff tears who develop localized calcium pyrophosphate disease may be predisposed to further proximal migration and further joint destruction. This situation poses a dilemma for the treating physician. Many patients with massive rotator cuff tears remain stable and require little or no treatment. Occasionally, symptomatic patients can be treated by arthroscopic débridement of the cuff tear. In a recent study, patients with massive rotator cuff tears without arthritis did well when treated with reverse total shoulder arthroplasty.¹¹⁵ It is crucial to define the patient who will proceed to the syndrome of cuff-tear arthropathy. If crystal deposition disease predisposes patients to proximal migration and joint destruction, joint aspiration with crystal analysis and scintigraphy to determine synovial reaction may be helpful diagnostic tools.

Hamada and co-workers¹⁶² followed 22 patients with massive rotator cuff tears treated conservatively. Radiographic findings included narrowing of the acromiohumeral interval and degenerative changes in the humeral head, tuberosities, acromion, AC joint, and glenohumeral joint. Five of seven patients followed for longer than 8 years progressed to cuff-tear arthropathy. Investigators concluded that progressive radiographic changes were associated with repetitive use of the arm in elevation, rupture of the long head of the biceps, impingement of the humeral head against the acromion, and weakness of external rotation.¹⁶²

Septic Arthritis

Septic arthritis can masquerade as any of the conditions classified as periarticular or glenohumeral disorders (see Chapters 99 and 110). Sepsis must be included in any differential diagnosis of shoulder pain because early recognition and prompt treatment are necessary to achieve a good functional result. The diagnosis is confirmed by joint aspiration with synovial fluid analysis and culture. Cultures should include aerobic, anaerobic, mycobacterial, and fungal studies.

Labral Tears

The glenoid labrum increases the depth of the glenoid and serves as an anchor for the attachment of the glenohumeral ligaments. Historically, labral tears have been difficult to diagnose. Findings on physical examination can be confused with impingement and rotator cuff tendinopathy and bicipital tendinitis. Diagnosis can be confirmed with MRI-arthrography, CT-arthrography, and DCAT.²⁷ Arthroscopy has greatly increased our knowledge of the glenoid labrum in normal and pathologic situations and has aided clinicians in the diagnosis and treatment of labral lesions.

Labral tears can be divided into tears associated with symptoms of internal derangement and tears associated with

anterior or posterior instability. A soft tissue Bankart lesion is associated with a tear of the anterior band of the inferior glenohumeral ligament and with anterior instability. Isolated labral tears that do not involve detachment of the ligaments can cause internal derangement and may have an arthroscopic appearance similar to that of a meniscal tear of the knee.

Andrews and associates⁷ first described lesions of the anterior superior labrum in throwing athletes; these lesions were often associated with biceps tendon tears (10%), which may result from traction of the biceps tendon. Snyder and co-workers¹⁶³ introduced the term *SLAP lesion* in 1990 to describe an injury involving the long head of the biceps tendon and the superior portion of the glenoid labrum.

The long head of the biceps tendon originates at the supraglenoid tubercle and the glenoid labrum in the superior-most portion of the glenoid. The major portion of the tendon blends with the posterior superior aspect of the labrum. The most common mechanism of a SLAP injury is a fall onto an outstretched arm with the shoulder in abduction and slight forward flexion.¹⁶³ The lesion also can result from acute traction on the arm and from an abduction and external rotation mechanism.^{164,165}

Patients usually complain of pain with overhead activities and a frequent catching or popping sensation in the shoulder. The most reliable diagnostic test is O'Brien's test. The test is performed against resistance with the arm in forward flexion and with the elbow extended and the forearm pronated. In the second part of the test, the arm is supinated. Less pain during the latter part of the test suggests a SLAP lesion.¹⁶³ The most accurate diagnostic test is MRI-arthrography with gadolinium.¹⁶⁶ Treatment for symptomatic SLAP lesions is surgical.

Adhesive Capsulitis

Adhesive capsulitis, or frozen shoulder syndrome (FSS), is a condition characterized by limited motion of the shoulder joint with pain at the extremes of motion. It was first described by Putman¹⁶⁷ in 1882 and later by Codman.¹ The initial presentation is pain, which is generalized and is referred to the upper arm, back, and neck. As pain increases, loss of joint motion ensues. The process generally is self-limiting and in most cases resolves spontaneously within 10 months, unless an underlying problem is present.

The exact cause of FSS is unknown.^{92,168} It is frequently associated with conditions such as diabetes mellitus, parkinsonism, thyroid disorders, and cardiovascular disease. When one of these conditions exists, a history of some mild trauma that initiated the frozen shoulder is often reported. Major skeletal trauma and soft tissue injury may coexist with FSS. It also may be seen with a variety of other conditions, including apical lung tumor, pulmonary tuberculosis, cervical radiculopathy, and post myocardial infarction.¹⁶⁹⁻¹⁷¹ In one review of FSS, 3 of 140 patients with this syndrome had local primary invasive neoplasms.¹⁷² Another study described 3 patients with adhesive capsulitis who subsequently were found to have a neoplastic lesion of the midshaft of the humerus.¹⁷³ In a high-risk patient with an underlying disorder, even minor surgery or trauma in a remote location, such as the hand, can precipitate FSS.^{92,174,175}

The pathophysiology involves a diffuse inflammatory synovitis with subsequent adherence of the capsule and loss of the normal axillary pouch and joint volume, which leads to significant loss of motion. Capsular contracture is thought to result from adhesion of the capsular surfaces or fibroblastic proliferation in response to cytokine production.^{168,174,176} The condition is common in women in their 40s and 50s. Typically, the patient relays a history of diffuse, dull aching around the shoulder, with weakness and loss of motion occurring over a few months.

Usually, three distinct clinical stages of the syndrome can be identified. Stage one is the painful inflammatory or freezing phase. During this stage, pain is severe, is exacerbated by any attempts at movement, and usually lasts a few weeks or months. The patient usually feels most comfortable with the arm at the side in an adducted and internally rotated position. Phase two, the adhesive or stiffening phase, generally lasts 4 to 12 months. Pain is usually minimal during this phase, although periscapular symptoms may develop from compensatory motion to achieve elevation of the arm. The third phase of the syndrome is the resolution or thawing phase, which may last 5 to 26 months. During this time, pain eases and motion slowly improves, although some patients may improve dramatically over a short period.¹⁷⁷

In the early stages, any attempts at motion may produce severe pain and associated weakness. The syndrome usually is associated with a prolonged period of immobilization.¹⁷⁸ Night pain is common, along with an inability to sleep on the associated shoulder; this is similar to findings of impingement syndrome.

In patients with a history of minimal or no trauma and FSS, a metabolic cause should be excluded. Complete blood cell count, erythrocyte sedimentation rate, serum chemistry, and thyroid function tests are done as a screening panel. Further testing is done if results suggest that the patient may have a systemic illness. Plain radiographs should include true anteroposterior, axillary, and scapular Y views of the shoulder. In patients with no underlying detectable illness and a negative workup, a Tc 99m pertechnetate scan may show increased uptake in FSS, but more important, it is used to exclude occult lesions or metastasis.¹⁷⁹

Literature review reveals a multitude of treatment options along with significant deficits on accurate reporting of disease staging with response to treatment.¹⁸⁰

Treatment of FSS is mainly conservative and consists of intra-articular injections, heat, gentle stretching, NSAIDs, and modalities such as transcutaneous electrical nerve stimulation. The disease usually is self-limited and after the painful phase is not severely disabling. Communication between the physician and the patient, together with a thorough explanation of the condition, is essential because resolution of the syndrome occurs slowly over time. Closed manipulation and surgery (open and arthroscopic) are reserved for patients whose condition is recalcitrant to conservative measures, or for whom the diagnosis is in question. Paramount in the prevention of FSS is avoiding overimmobilization in a minor shoulder injury, in addition to careful identification of patients at risk for FSS.

Fareed and Gallivan¹⁸¹ reported good results with hydraulic distention of the glenohumeral joint using local anesthetic agents. Rizk and associates¹⁸² conducted a prospective,

randomized study to assess the effects of steroid or local anesthetic injection in 48 patients with FSS. No significant difference in outcome was noted between individuals who received intrabursal or intra-articular injection. Steroid with lidocaine offered no advantage over lidocaine alone in restoring shoulder motion. However, transient pain relief occurred in two-thirds of steroid-treated patients.¹⁸²

General anesthesia occasionally is indicated for closed manipulation. Hill and Bogumill¹⁸³ reported the results of manipulation of 17 frozen shoulders in 15 patients who did not respond to physical therapy. On average, 78% of individuals who were working before their shoulder problems returned to work 2.6 months after manipulation. Investigators concluded that manipulation allowed patients to return to a normal lifestyle and to work sooner than the reported natural history of the condition.¹⁸³ Surgical intervention for adhesive capsulitis should be limited to treatment of an underlying problem, such as calcific tendinitis or an impingement syndrome.

Glenohumeral Instability

Glenohumeral instability is a pathologic condition that manifests as pain associated with excessive translation of the humeral head on the glenoid during shoulder motion. Instability can range from excessive laxity with episodes of subluxation to frank dislocation of the joint. Traumatic dislocation of the glenohumeral joint reveals characteristic clinical and radiographic findings that are beyond the scope of this chapter and have been reviewed in detail elsewhere.¹⁸⁴ The most common type of instability is anterior, although posterior and multidirectional laxity of the shoulder is increasingly recognized as a cause of shoulder pain. Anterior dislocation usually occurs with the arm in an abducted and externally rotated position, and the diagnosis is usually obvious. Posterior dislocation is frequently associated with convulsive disorders or unusual trauma with the arm in a forward flexed and internally rotated position. The diagnosis is often missed and should always be suspected in the patient who is unable to rotate the arm externally after trauma.

Recurrent subluxation without dislocation may be difficult to diagnose and may be mistakenly identified as impingement with chronic cuff tendinitis. An overhead athlete may experience repetitive stresses to the shoulder, causing microtrauma to the static stabilizers. Jobe and colleagues²¹ described a syndrome of shoulder pain in overhead or throwing athletes that manifests as impingement but is caused by anterior subluxation of the joint, with the humeral head impinging on the anterior aspect of the coracoacromial arch. Fu and co-workers¹⁸⁵ underscored this distinction by dividing the causes of rotator cuff tendinitis into primary impingement of the tendon on the coracoacromial arch and anterior subluxation with secondary impingement in young athletes performing overhead movements. Walch and colleagues¹⁸⁶ described intra-articular impingement between the undersurface of the rotator cuff (supraspinatus and infraspinatus) and the posterior superior glenoid rim and labrum. This “internal impingement” usually is observed in overhead athletes with subtle anterior glenohumeral instability and results in tendinitis or partial tears of the rotator cuff (see Figure 46-16).

The diagnosis of glenohumeral instability with subluxation in one or multiple directions is made with the combination of a detailed history and physical examination and the use of adjuncts, such as arthrography, CT, MRI, and arthroscopy with examination under anesthesia. The syndrome of multidirectional instability has been recognized in patients with symptomatic inferior instability, in addition to anterior or posterior instability. Approximately 50% of affected patients have evidence of generalized laxity. Frequently, the syndrome occurs in young athletic patients who are loose jointed, in particular in the dominant arm of pitchers, racket sports players, and swimmers. In this type of athlete, repetitive microtrauma may cause stretching of the shoulder, resulting in a large capsular pouch without labral detachment. A traumatic event may damage the shoulder, resulting in the syndrome of multidirectional instability and a Bankart lesion.¹⁸⁷

The most common manifestation in these patients is pain, which is often mistakenly considered to be rotator cuff tendinitis. The patient may relate a history of minor trauma causing acute pain and a “dead arm” syndrome lasting minutes or hours. Other associated symptoms include a sense of instability, weakness, and radicular symptoms suggestive of neuropathy. Few or no positive physical findings may be associated with chronic subluxation or multidirectional instability. The patient may have signs of generalized ligamentous laxity, and pain may be reproduced by subluxating the glenohumeral joint in multiple directions. One particularly helpful sign of inferior laxity is the sulcus sign, which refers to the subacromial indentation that occurs when longitudinal traction is applied to the humerus with the arm at the side. This sign occurs with inferior translation of the humeral head. Because this syndrome frequently occurs in athletes with highly developed musculature around the shoulder girdle, physical findings of subluxation may be difficult to reproduce in the office setting.

Plain radiographs are generally normal, although some inferior subluxation may be shown on stress radiographs obtained with the use of weights. Special radiographs, as discussed previously, may show a Bankart lesion (i.e., avulsion of the anterior inferior glenoid rim) or a Hill-Sachs lesion (i.e., osteochondral defect of the posterior humeral head) with subluxation of the humeral head in front of the anterior glenoid rim. CT-arthrography or MRI-arthrography may show increased capsular volume, a labral detachment, or a Hill-Sachs lesion (see Figure 46-9). When surgery is indicated, examination under anesthesia and shoulder arthroscopy may assist in diagnosing the primary direction of instability in the syndrome of multidirectional instability. In selected patients with traumatic anterior dislocation who have no history of multidirectional instability, arthroscopic stabilization may be done with stabilization of the capsulolabral complex.

Treatment of patients with chronic subluxation or the syndrome of multidirectional instability is first directed toward prolonged rehabilitation. Activities that stress the shoulder and produce symptoms are avoided. Strengthening exercises of the shoulder girdle may control symptoms, dynamically stabilizing the glenohumeral joint, and may obviate the need for surgical intervention. If a conservative treatment program fails, surgery is performed on the side associated with the greatest clinical instability. Stabilization

is directed toward tightening of the capsular structures to stabilize the glenohumeral joint.^{187,188}

EXTRINSIC OR REGIONAL FACTORS CAUSING SHOULDER PAIN

Because the shoulder girdle connects the thorax with the upper extremity, and because major neurovascular structures pass in proximity to the joint, shoulder pain is a hallmark of many nonarticular conditions.

Cervical Radiculopathy

Cervical pathology may manifest with associated shoulder pain. The area of referred pain has a dermatomal pattern, consistent with the distribution of dermatomal nerve roots. Isolation of the pain usually defines the exact location of associated cervical pathology. Pain can be differentiated from shoulder pain on the basis of history, physical examination, EMG, cervical radiographs, and myelography or MRI when indicated. Because conditions causing cervical neck pain and conditions causing shoulder pain, such as calcific tendinitis and cervical radiculopathy, may coexist, it is often difficult to distinguish which lesion is responsible for the symptoms. These conditions often can be differentiated by injection of local anesthetics to block certain components of the pain.

The thoracic outlet is an interval created by the anterior and middle scalene muscles and the first rib through which the brachial plexus and vessels pass to the arm. In thoracic outlet syndrome, compression of these nerves and vessels often manifests as vague shoulder pain with numbness of the ipsilateral fourth and fifth digits. Cervical rib or hypertrophy of the scalene muscles can be related to the onset of pain.¹⁸⁹⁻¹⁹¹ The occurrence of pain also has been related to scapular ptosis, poor posture, and clavicular fracture with malunion or copious formation of callus.

Brachial Neuritis

In the 1940s, Spillane¹⁹² and Parsonage and Turner^{193,194} described a painful condition of the shoulder associated with limitation of motion. As pain subsided and motion improved, muscle weakness and atrophy became apparent. The deltoid, supraspinatus, infraspinatus, biceps, and triceps are the most frequently involved muscles,¹⁹⁵ although diaphragmatic paralysis also has been reported.^{194,196} The cause is unclear, but the clustering of cases suggests a viral or postviral syndrome.^{193,194} Occasionally, an associated influenza-like syndrome or previous vaccination has been reported.¹⁹⁵

Hershman and colleagues¹⁹⁷ described acute brachial neuropathy in athletes. Findings that suggest an acute brachial neuropathy include acute onset of pain without trauma; persistent, severe pain that continues despite rest; and patchy neurologic signs. The diagnosis is confirmed by EMG and nerve conduction studies.¹⁹⁷ The prognosis for recovery is excellent, although full recovery may take 2 to 3 years. Tsairis and associates¹⁹⁸ reported 80% recovery within 2 years and more than 90% recovery by the end of 3 years.

Nerve Entrapment Syndromes

Peripheral compression neuropathies of the upper extremities may produce referral pain to the shoulder. Distant compression neuropathies, such as carpal tunnel (median nerve) and cubital tunnel (ulnar nerve) syndromes, may manifest with concomitant and separate shoulder impingement with rotator cuff disease. Associated numbness and paresthesias with mapping of the dermatomal distribution and with peripheral neuropathy often direct the examiner to the appropriate diagnosis. Patients often give a history of dropping objects and a feeling of clumsiness with the affected hand. A Tinel sign may be elicited over the region of entrapment at the elbow or wrist. Provocative maneuvers such as Phalen's test may be positive and usually indicate median nerve compression at the wrist. Diminished vibratory sensation is an early finding in the disease and is easily reproducible,^{199,200} whereas decreased two-point discrimination and intrinsic atrophy are late findings of peripheral compression neuropathy.¹⁹⁹

The diagnosis usually can be made by clinical examination with exclusion of other possible causes. EMG and nerve conduction velocity tests may reveal slowed conduction and latency at appropriate compression points to aid in diagnosis. Spinal accessory nerve injury with subsequent denervation of the trapezius may cause weakness and pain in the shoulder consistent with impingement. The injury can occur from traction injury to the neck or a direct blow or pressure to the base of the neck. Iatrogenic nerve injury may result from surgical procedures on the neck such as lymph node biopsy.²⁰¹ The injury produces weakness in shoulder abduction with associated pain that radiates from the neck into the trapezius and shoulder. Subsequent atrophy of the trapezius may lead to dyssymmetry and ptosis of the involved shoulder, with narrowing of the supraspinatus outlet and secondary impingement with shoulder pain. Definitive diagnosis can be made by EMG examination.

Early treatment is conservative. If return of function is not evident at 6 months, surgical exploration of the nerve with possible tendon transfers may be indicated.²⁰²

Injury to the long thoracic nerve (cervical fifth, sixth, and seventh roots) can lead to scapular winging. The resultant scapular dysrhythmia and weakness can lead to a painful shoulder that may mimic rotator cuff disease.²⁰¹ Patients also complain of pain and discomfort with active forward flexion of the shoulder. Patients who remain symptomatic after conservative treatment may require surgery for scapulothoracic fusion or tendon transfer with use of the pectoralis major or minor to stabilize the scapula.^{203,204}

In quadrilateral space syndrome, the axillary nerve is compressed by fibrous bands in the quadrilateral space.^{201,205,206} This syndrome typically occurs when the arm is held in abduction and external rotation, with subsequent tightening of fibrous bands across the nerve.²⁰⁷ It is most commonly seen in the dominant shoulder of young athletic individuals such as pitchers, tennis players, and swimmers who function with excessive overhead activity. Pain may occur throughout the shoulder girdle and may radiate down the arm in a nondermatomal pattern. Neurologic and EMG testing may be normal. Diagnosis often is made by an arteriogram of the subclavian artery. A positive arteriogram reveals compression of the posterior humeral circumflex artery as it

traverses the quadrangular space when the arm is in the abducted and externally rotated position. Surgical intervention may be required to release the fibrotic bands or the tendon of the teres minor if the patient fails conservative treatment.^{201,208}

Suprascapular nerve entrapment syndrome can be caused by a traction lesion resulting from repetitive overhead activities, a compression lesion, or both, to the nerve, caused by tethering of the nerve at the suprascapular notch by the suprascapular ligament, or the spinoglenoid notch by the transverse ligament. It also can result from direct compression of a space-occupying lesion, such as a ganglion or a lipoma. Rengachary and co-workers²⁰⁹ described variations in size and shape of the suprascapular notch that may predispose the nerve to entrapment. Several authors have noted an association of suprascapular neuropathy with massive rotator cuff tears, presumably resulting from a traction injury to the nerve.^{210,211}

The resulting suprascapular neuropathy produces pain in the posterolateral aspect of the shoulder that may radiate into the ipsilateral extremity, shoulder, or side of the neck. Although this condition is uncommon, it can have a prolonged and disabling course when undiagnosed. Because the suprascapular nerve has no cutaneous innervation, no numbness, tingling, or paresthesias are associated. Weakness is usually noted in abduction and external rotation, and significant atrophy is often observed at diagnosis. The pain frequently is described as a deep burning or aching that can be well localized and often can be elicited by palpation over the region of the suprascapular notch. Any activity that brings the scapula forward, such as reaching across the chest, may aggravate the pain.²¹² The location of pain and other symptoms can mimic more common entities, such as impingement, rotator cuff disease, cervical disk disease, brachial neuropathy, biceps tendinitis, thoracic outlet syndrome, AC disease, and instability of the shoulder.²¹³

Fritz and colleagues²¹⁴ reported the efficacy of MRI in the diagnosis of suprascapular nerve entrapment secondary to space-occupying lesions. Definitive diagnosis is made with EMG and nerve conduction studies. EMG changes usually reveal spontaneous activity in the muscle at rest and fibrillations indicating motor atrophy and denervation. Nerve conduction studies may reveal slowing across the site of entrapment. As with axillary nerve entrapment, the syndrome is often associated with young, athletic individuals with excessive overhead activity.²¹⁵ It also has been associated with trauma.^{213,216,217}

Lack of consensus continues regarding the optimal treatment of suprascapular neuropathy.^{6,213,215,218-220} Post and Grinblat²¹⁸ reported good to excellent results with surgical treatment in 25 of 26 cases. No difference in residual atrophy and in strength deficits has been shown, however, for operative and nonoperative treatments. Ferretti and co-workers²¹⁵ evaluated 96 top-level volleyball players from the 1985 European Championships and found that 12 had isolated suprascapular neuropathy with atrophy of the infraspinatus of the dominant shoulder. All players were unaware of any impairment, however, and played without limitations. After a space-occupying lesion has been excluded, a 6-month trial of conservative treatment may be indicated for some individuals. If the entrapment does not improve, or if symptoms worsen with conservative treatment, surgical

decompression for pain relief is warranted; however, resolution of atrophy and strength gains can vary.²¹³

Sternoclavicular Arthritis

Occasionally, traumatic, nontraumatic, or infectious conditions can cause pain around the sternoclavicular joint (see Figure 46-1). The most common problem involves ligamentous injury and painful subluxation or dislocation. This can be diagnosed by palpable instability and crepitus over the sternoclavicular joint. Sternoclavicular views may radiographically show dislocation.²²¹

Inflammatory arthritis of the sternoclavicular joint has been associated with rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, and septic arthritis. The association of palmoplantar pustulosis with sternoclavicular arthritis has been reported.²²² Seven of 15 patients who underwent biopsy for this condition had cultures positive for *Propionibacterium acnes*, suggesting an infectious origin of the condition.²²²

Two other conditions involving the sternoclavicular joint are Tietze's syndrome, a painful, nonsuppurative swelling of the joint and adjacent sternochondral junctions, and Friedrich's syndrome, a painful osteonecrosis of the sternal end of the clavicle.³ Condensing osteitis of the clavicle is a rare benign idiopathic lesion of the medial one-third of the clavicle. This condition, which is better described as aseptic enlarging osteosclerosis of the clavicle, is most commonly seen in middle-aged women and manifests as a tender swelling over the medial one-third of the clavicle.²²³

Reflex Sympathetic Dystrophy

Since its original description by Mitchell²²⁴ in 1864, reflex sympathetic dystrophy (RSD) has remained a poorly understood and frequently overlooked condition. Its cause is unknown but may be related to sympathetic overflow or short-circuiting of impulses through the sympathetic system. Any clinician who deals with painful disorders must be familiar with the diagnosis and treatment of this condition. Bonica's²²⁵ excellent review covers the clinical presentation, various stages of the disease, and the importance of early intervention to ensure a successful outcome.

RSD has been called *causalgia*, *shoulder-hand syndrome*, and *Sudeck's atrophy*, which has caused some confusion. It is generally associated with minor trauma and is to be differentiated from causalgia, which involves trauma to major nerve roots.²²⁴ RSD is divided into three phases, which are important in determining appropriate treatment.²²⁵ Phase one is characterized by sympathetic overflow with diffuse swelling, pain, increased vascularity, and radiographic evidence of demineralization. If left untreated for 3 to 6 months, the condition may progress to phase two, which is characterized by atrophy. The extremity may now be cold and shiny, with atrophy of the skin and muscles. Phase three refers to progression of trophic changes, with irreversible flexion contracture and a pale, cold, painful extremity. It has been speculated that phase one is related to peripheral short-circuiting of nerve impulses, phase two represents short-circuiting through the internuncial pool in the spinal cord, and phase three is controlled by higher thalamic centers.^{225,226}

Steinbrocker²²⁷ reported that recovery is possible as long as vasomotor activity with swelling and hyperemia is evident. After the trophic phase two or three is established, the prognosis for recovery is poor. Prompt recognition of the syndrome is important because early intervention to control pain is mandatory. Careful supervision and reassurance are crucial because many of these patients are emotionally labile as a result of the pain or an underlying problem. The syndrome may be remarkably reversed by a sympathetic block. Patients who receive transient relief from sympathetic blockade may be helped by surgical sympathectomy.

Neoplasms

Primary and metastatic neoplasms may cause shoulder pain by direct invasion of the musculoskeletal system or by compression with referred pain.^{2,228} Primary tumors are more likely to occur in younger individuals. More common lesions have a typical distribution, such as the predilection of a chondroblastoma for the proximal humeral epiphysis or an osteogenic sarcoma for the metaphysis.²²⁹ The differential diagnosis of spontaneous onset of shoulder pain in older individuals should include metastatic lesions and myeloma. Neoplasms are best identified by plain radiographs, MRI, Tc 99m MDP scintigraphy, and CT.

Neoplasms also may involve the shoulder region through metastases to the region. An associated history of carcinomas should alert the examiner to the possibility of a bone tumor, especially in patients who have had malignancies with a predilection for metastasis to bone (e.g., thyroid, renal, lung, prostate, breast). Pain often is present at rest and is exacerbated at night. Atypical pain distribution that is not relieved by injection without specific dermatomal distribution should alert the examiner to other underlying possibilities. Plain radiographs should be evaluated thoroughly for any cortical destruction and for lytic lesions.

Pancoast syndrome or apical lung tumor may manifest as shoulder pain or cervical radiculitis caused by invasion of the brachial plexus or invasion of C8 or T1 roots.²³⁰⁻²³² With invasion of the cervical sympathetic chain, the patient also may develop Homer's syndrome.

Miscellaneous Conditions

With increasing numbers of patients undergoing long-term maintenance hemodialysis, a shoulder pain syndrome known as *dialysis shoulder arthropathy* has been described. It consists of shoulder pain, weakness, loss of motion, and functional limitation. The cause and pathogenesis of this syndrome are unclear, although rotator cuff disease, pathologic fracture, bursitis, and local amyloid deposition have been implicated as causative factors.²³³ Surgical or necropsy data are insufficient to confirm a specific diagnosis. Patients generally respond poorly to local measures of injection, heat, and NSAIDs, but their condition may improve with correction of underlying metabolic disorders, such as osteomalacia and secondary hyperparathyroidism.

In patients older than 50 years of age with bilateral shoulder pain and stiffness, polymyalgia rheumatica should be considered as a diagnosis. It is twice as common among females and is almost exclusively found in whites.²³⁴ Most

patients have sedimentation rates greater than 40 mm/hr and respond to low doses of corticosteroids.²³⁵

Low Back Pain

RAJIV DIXIT

KEY POINTS

Up to 80% of the population will experience low back pain (LBP), and degenerative changes of the lumbar spine is the most common cause.

More than 90% of these patients are largely pain free within 8 weeks.

Initial evaluation should identify the few patients with neurologic involvement or suspicion of systemic disease (infection, malignancy, or spondyloarthritis) because they may need urgent or specific intervention.

Psychosocial and other factors that predict risk of chronic disabling LBP should be assessed.

Imaging is rarely indicated in the absence of significant neurologic involvement or suspicion of systemic disease.

Imaging abnormalities should be carefully interpreted because they are frequently present in asymptomatic individuals.

A precise pathoanatomic diagnosis with identification of the pain generator cannot be made in up to 85% of patients.

Persistent LBP should be treated with an individually tailored program that includes analgesia, core strengthening, stretching, aerobic conditioning, loss of excess weight, and patient education.

Intensive interdisciplinary rehabilitation with an emphasis on cognitive-behavioral therapy should be strongly considered if conservative measures fail.

There is no evidence for the effectiveness of epidural corticosteroid injections in patients without radiculopathy.

A large number of injection techniques, physical therapy modalities, and nonsurgical interventional therapies lack evidence of efficacy.

The major indication for back surgery is presence of a serious or progressive neurologic deficit.

Back surgery in the absence of neurologic deficits, especially spinal fusion for degenerative changes, is not clearly effective.

EPIDEMIOLOGY

Low back pain (LBP) is one of the most common conditions encountered in clinical medicine. It affects the area between the lower rib cage and gluteal folds.

An estimated 65% to 80%¹ of the population will experience LBP during their lifetime. LBP is the most prevalent chronic pain syndrome and the leading cause of limitation

of activity in patients younger than the age of 45. It is also the second most frequent reason for a visit to the physician's office and the third most common surgical indication.² The incidence of LBP increases with age, and LBP more commonly affects women.

The natural history of back pain, especially the duration and chronicity, remains somewhat controversial. Regardless, studies show that pain and function improve substantially in most patients within 1 month,³ and more than 90% are better at 8 weeks.⁴ These patients, however, remain susceptible to future relapses that also tend to be brief. The remaining 7% to 10% develop chronic LBP and it is these individuals who are largely responsible for the high costs associated with LBP. The most recent reliable data, from 1998, estimated the direct cost of managing LBP in the United States to be \$90 billion⁵ with substantial additional indirect costs due to lost time from work and decreased productivity.

A number of risk factors have been associated with LBP including heredity, psychosocial factors, heavy lifting, obesity, pregnancy, weaker trunk strength, and cigarette smoking.⁶ Persistence of disabling LBP has been associated with the presence of maladaptive pain coping behavior, nonorganic signs, functional impairment, poor general health status, and psychiatric comorbidities.⁷

ANATOMY

The lumbar spine is composed of five vertebrae. Each vertebra consists of a body anteriorly and a neural arch that encloses the spinal canal posteriorly (Figure 47-1). Their cartilaginous end plates cover the superior and inferior surfaces of the vertebral body.

Adjacent vertebrae are united by an intervertebral disk. The outer circumference of the disk is made up of concentric layers of dense, tough fibrous tissue, the annulus fibrosus. The annulus encloses a shock-absorbing gelatinous nucleus pulposus. In addition to this discovertebral joint anteriorly, at each level of the lumbar spine, there are two posterolaterally placed synovial facet (apophyseal) joints. These are formed by articulation of the superior and inferior articular processes of adjacent vertebrae.

The vertebral column is further stabilized by ligaments and paraspinal muscles (erector spinae, trunk, and abdominal muscles). The anterior and posterior longitudinal ligaments run the length of the spinal column. They anchor the anterior and posterior vertebral body surfaces and intervertebral disks. The ligamentum flavum interconnects the laminae while the interspinous and supraspinous ligaments interconnect the spinous processes. The intertransverse ligaments interconnect the transverse processes.

Figure 47-1 Anatomy of the lumbar spine. **A**, Cross-sectional view through a lumbar vertebra. **B**, Lateral view of the lumbar spine.

The sacroiliac joints join the spinal column to the pelvis. The anterior and inferior part of the joint is lined with synovium, whereas the posterior and superior part is fibrous. There is little or no movement at the sacroiliac joint.

The spinal canal in the lumbar region contains the cauda equina (the bundle of lumbar and sacral nerve roots that occupy the vertebral canal below the cord), blood vessels, and fat. Because the spinal cord ends at the L1 level, cord compression is generally not a feature of lumbar pathology. At each level a pair of nerve roots leaves the spinal canal and exits through the intervertebral foramina.

CLINICAL EVALUATION

LBP has a large number of causes, and the spectrum of clinical presentation is broad. Many individuals will have self-limited episodes of acute LBP that resolve without specific treatment, whereas others may present with recurrent or chronic LBP. A thorough history is the most important part of the clinical evaluation of these patients. Imaging is often unnecessary.

HISTORY

The major focus in the initial evaluation of a patient with LBP is to identify the small fraction⁸ (<5%) of patients who may have neural compression or underlying systemic disease (infection, malignancy, or spondyloarthritis) as the cause of back pain. These patients require early diagnostic testing and may require specific treatment (e.g., antibiotics for vertebral osteomyelitis) or urgent treatment (e.g., surgical decompression in a patient with major or progressive neural compression). As such, clues to the presence of underlying systemic disease⁹⁻¹¹ (Table 47-1), often referred to as “red flags,” should be carefully sought. It is also important to look for any social or psychologic distress such as job dissatisfaction, pursuit of disability compensation, and depression that may amplify or prolong the pain.¹¹

Mechanical LBP is due to an anatomic or functional abnormality in the spine that is not associated with inflammatory or neoplastic disease. It typically increases with physical activity and upright posture and tends to be relieved by rest and recumbency. More than 95% of LBP

is mechanical,⁸ and degenerative change in the lumbar spine is the most common cause of mechanical LBP.⁹ Severe and acute mechanical LBP in a postmenopausal woman would be suspicious for a vertebral compression fracture secondary to osteoporosis. Nocturnal pain suggests the possibility of underlying infection or neoplasm as the cause of LBP.

Inflammatory LBP,¹² as seen in the spondyloarthritides, is more common in men younger than 40 years of age. It is associated with marked morning stiffness that usually lasts for more than 30 minutes. The pain frequently improves with exercise but not with rest. Pain is often worse during the second half of the night, and some patients complain of alternating buttock pain.

It is important to ask the patient if the back pain radiates into the lower extremities, suggesting pseudoclaudication

Table 47-1 Red Flags for Potentially Serious Underlying Causes of Low Back Pain

Spinal Fracture
Significant trauma
Prolonged glucocorticoid use
Age > 50 yr
Infection or Cancer
History of cancer
Unexplained weight loss
Immunosuppression
Injection drug use
Nocturnal pain
Age > 50 yr
Cauda Equina Syndrome
Urinary retention
Overflow incontinence
Fecal incontinence
Bilateral or progressive motor deficit
Saddle anesthesia
Spondyloarthritis
Severe morning stiffness
Pain improves with exercise, not rest
Pain during second half of night
Alternating buttock pain
Age < 40 yr

(neurogenic claudication) secondary to spinal stenosis or sciatica (usually secondary to a herniated disk). Young adults are more likely to experience disk herniations, and elderly patients are more likely to have spinal stenosis. Sciatica results from nerve root compression and produces pain in a dermatomal (radicular) distribution, usually to the level of the foot or ankle. The pain is lancinating, shooting, and sharp in quality. It is frequently accompanied by numbness and tingling and may be accompanied by sensory and motor deficits. Sciatica due to disk herniation typically increases with cough, sneezing, or the Valsalva maneuver. Sciatica should be differentiated from non-neurogenic sclerotomal pain. This pain can arise from pathology within the disk, facet joint, or lumbar paraspinal muscles and ligaments. Like sciatica, sclerotomal pain is often referred into the lower extremities, but unlike sciatica, sclerotomal pain is nondermatomeal in distribution, it is dull in quality, and the pain usually does not radiate below the knee or have associated paresthesias. Most radiant pain is sclerotomal.⁹ Bowel or bladder dysfunction should suggest the possibility of the cauda equina syndrome.

PHYSICAL EXAMINATION

A physical examination usually does not lead to a specific diagnosis. Nevertheless, a general physical examination including a careful neurologic examination may help identify those few but critically important cases of LBP that are secondary to a systemic disease or have clinically significant neurologic involvement (see Table 47-1).

Inspection may reveal the presence of scoliosis. This can be either structural or functional. A structural scoliosis is associated with structural changes of the vertebral column and sometimes the rib cage as well. In adults structural scoliosis is usually secondary to degenerative changes, although some adults may have a history of adolescent idiopathic scoliosis. With forward flexion, structural scoliosis persists. In contrast, functional scoliosis, which usually results from paravertebral muscle spasm or leg length discrepancy, usually disappears. A tuft of hair in the lumbar spine region may indicate a congenital structural abnormality such as spina bifida occulta.

Palpation can detect paravertebral muscle spasm. This often leads to loss of the normal lumbar lordosis. Point tenderness on percussion over the spine has sensitivity but not specificity for vertebral osteomyelitis. A palpable step-off between adjacent spinous processes suggests spondylolisthesis.

Limited spinal motion (flexion, extension, lateral bending, and rotation) is not associated with any specific diagnosis because LBP due to any cause may limit motion. Range of motion measurements, however, can help in monitoring treatment.⁶ Chest expansion of less than 2.5 cm has specificity but not sensitivity for ankylosing spondylitis.¹²

The hip joints should be examined for any decrease in range of motion because hip arthritis, which normally causes groin pain, may occasionally present as LBP. Trochanteric bursitis with tenderness over the greater trochanter of the femur can be confused with LBP. The presence of more widespread tender points, especially in a female patient, suggests the possibility that LBP may be secondary to fibromyalgia.

In patients with a history of LBP that radiates into the lower extremities (sciatica, pseudoclaudication, or referred sclerotomal pain) a straight leg-raising test should be performed. With the patient lying on his or her back, the heel is placed in the palm of the examiner's hand. With the knee fully extended the leg is raised progressively. This places tension on the sciatic nerve (that takes origin from L4, L5, S1, S2, and S3) and thereby stretches the nerve roots (especially L5, S1, and S2). If any of these nerve roots is already irritated, such as by impingement from a herniated disk, further tension on the nerve root by straight leg-raising will result in radicular pain that extends below the knee. The test is positive if radicular pain is produced when the leg is raised less than 70 degrees. Dorsiflexion of the ankle further stretches the sciatic nerve and increases the sensitivity of the test. Pain experienced in the posterior thigh or knee during straight leg-raising is generally from hamstring tightness and does not represent a positive test. The straight leg-raising test is sensitive but not specific for clinically significant disk herniation at the L4-5 or L5-S1 level (the sites of 95% of clinically meaningful disk herniations). False-negative tests are more frequently seen with herniation above the L4-5 level. The straight leg-raising test is usually negative in patients with spinal stenosis. The crossed straight leg-raising test (with sciatica reproduced when the opposite leg is raised) is highly specific but insensitive for a clinically significant disk herniation.^{6,11,13,14}

The neurologic evaluation (Figure 47-2) of the lower extremities in a patient with sciatica can identify the specific nerve root involved. The evaluation should include motor testing with focus on dorsiflexion of the foot (L4), great toe dorsiflexion (L5), and foot plantar flexion (S1); determination of knee (L4) and ankle (S1) deep tendon reflexes; and tests for dermatomeal sensory loss. The inability to toe walk (mostly S1) and heel walk (mostly L5) indicate muscle weakness. Muscle atrophy can be detected by circumferential measurements of the calf and thigh at the same level bilaterally.⁶

Patients involved with litigation or with psychologic distress occasionally exaggerate their symptoms. They may display nonorganic signs where the objective findings do not match the subjective complaints such as with nonanatomic motor or sensory loss. A number of tests to detect this have been described by Waddell and co-workers.¹⁵ The most reproducible tests are the presence of superficial tenderness, overreaction during the examination, and observation of a discrepancy in the straight leg-raising test done in the seated and supine positions.

DIAGNOSTIC TESTS

Imaging

The major function of diagnostic testing, especially imaging, is the early identification of pathology in those few patients who have evidence of a major or progressive neurologic deficit and those in whom an underlying systemic disease is suspected (see Table 47-1). Otherwise, imaging is not required unless significant symptoms persist beyond 6 to 8 weeks. This approach avoids unnecessary early testing because more than 90% of the patients will have recovered spontaneously by 8 weeks.^{6,8} Furthermore, neither magnetic

resonance imaging (MRI) nor plain radiographs obtained early in the course of LBP evaluation improves clinical outcome, predicts recovery course, or reduces the overall cost of care.^{2,16}

A significant problem with all imaging studies is that many of the anatomic abnormalities identified in patients with LBP are also commonly present in asymptomatic individuals and are frequently unrelated to the back pain.⁹ Often these abnormalities result from age-related degenerative changes, which begin to appear even in early adulthood and are among the earliest degenerative changes in the body.¹⁷ Although clinically challenging and sometimes impossible, one should refrain from making causal inferences based solely on imaging abnormalities in the absence of corresponding clinical findings because this may lead to unnecessary, invasive, and costly interventions.

Given the weak association between imaging abnormalities and symptoms, it is not surprising that in up to 85% of patients a precise pathoanatomic diagnosis with identification of the pain generator cannot be made.¹¹ Patients should understand that the reason for imaging is to rule out serious conditions and that common degenerative findings are expected. Ill-considered attempts to make a diagnosis on the basis of imaging studies may reinforce the suspicion of serious disease, magnify the importance of nonspecific findings, and label patients with spurious diagnoses.

Plain radiographs and MRI are the major modalities used in the evaluation of patients with LBP. In patients with persistent LBP of greater than 6 to 8 weeks' duration despite standard therapies, radiography may be a reasonable first option if there are no symptoms suggesting radiculopathy or spinal stenosis.¹⁸ Anteroposterior and lateral views are usually adequate. Oblique views substantially increase radiation exposure and add little new diagnostic information. Gonadal radiation in a woman from a two-view radiograph of the lumbar spine is equivalent to radiation exposure from a chest radiograph taken daily for more than 1 year.¹⁸

Abnormalities on radiography such as single-disk degeneration, facet joint degeneration, Schmorl's nodes (protrusion of the nucleus pulposus into the spongiosa of a vertebra), spondylolysis, mild spondylolisthesis, transitional vertebrae

(the "lumbarization" of S1 or "sacralization" of L5), spina bifida occulta, and mild scoliosis are equally prevalent in individuals with and without LBP.^{8,9,19}

MRI without contrast is generally the best initial test for patients with LBP who require advanced imaging. It is the preferred modality for the detection of spinal infection and cancers, herniated disks, and spinal stenosis.⁸ MRI testing for LBP should largely be limited to patients in whom there is a suspicion of systemic disease (such as infection or malignancy), for the preoperative evaluation of patients who are surgical candidates on clinical grounds^{11,18} (e.g., the presence of a significant or progressive neurologic deficit), or for those patients with radiculopathy or spinal stenosis who are candidates for epidural corticosteroids.¹⁸ Disk abnormalities are commonly noted on MRI studies but often have little or no relationship with the patient's symptoms. A disk bulge is a symmetric, circumferential extension of disk material beyond the interspace. A disk herniation is a focal or asymmetric extension. Herniations are subdivided into protrusions and extrusions. Protrusions are broad-based, whereas extrusions have a "neck" so that the base is narrower than the extruded material. Bulges (52%) and protrusions (27%) are common in asymptomatic adults, but extrusions are rare.⁸ MRI with the intravenous contrast agent, gadolinium, may be useful for the evaluation of patients with prior back surgery (with no hardware present) to help in the differentiation of scar tissue from recurrent disk herniation.

MRI is generally preferred over computed tomography (CT) scanning in the evaluation of patients with LBP. However, when bone anatomy is critical, CT is superior. Unlike MRI, CT can safely be done in patients with a ferromagnetic implant, although imaging artifacts may make interpretation difficult. CT myelography is therefore sometimes preferred in patients with surgically placed spinal hardware.

Bone scanning is used primarily to detect infection, bony metastases, or occult fractures and to differentiate them from degenerative changes. Bone scans have limited specificity due to poor spatial resolution, and thus abnormal findings often require further confirmatory imaging such as MRI.

Electrodiagnostic Studies

Electrodiagnostic studies can be helpful in the evaluation of some patients with lumbosacral radiculopathy. The main procedures are electromyography and nerve conduction studies. These studies can confirm nerve root compression and define the distribution and severity of involvement. Whereas studies such as MRI can only provide anatomic information, electrodiagnostic studies provide physiologic information that may support or refute the findings on imaging. Electrodiagnostic testing is therefore mostly considered in patients with persistent disabling symptoms of radiculopathy where there is discordance between the clinical presentation and findings on imaging. Electromyography and nerve conduction studies can also be helpful in differentiating the limb pain of peroneal nerve palsy or lumbosacral plexopathy from that of L5 radiculopathy. These studies are also useful in evaluating possible factitious weakness. Electrodiagnosis is unnecessary in a patient with an obvious radiculopathy. It should be noted that electromyographic changes depend on the development of muscle denervation following nerve injury and may not be detected for 2 to 3 weeks after the injury. Another limitation is that electromyographic abnormalities may persist for over a year following decompressive surgery.²⁰

Laboratory Studies

Laboratory studies are used mostly in identifying patients with systemic causes of LBP. A patient with normal blood cell counts, erythrocyte sedimentation rate, and radiographs of the lumbar spine is unlikely to have underlying infection or malignancy as the cause of LBP.²¹

DIFFERENTIAL DIAGNOSIS

LBP usually originates from pathology within the lumbar spine or associated muscles and ligaments (Table 47-2). Rarely pain is referred to the back from visceral disease. In the vast majority of patients with LBP, the pain is mechanical.¹¹ Degenerative change in the lumbar spine is the largest contributor to the mechanical causes of LBP⁸ (see Table 47-2) and indeed the most commonly identified cause of back pain.

Lumbar Spondylosis

The current common usage of the term *lumbar spondylosis* incorporates degenerative changes in both the anteriorly placed discovertebral joints and the posterolaterally placed facet joints.⁶ These degenerative or osteoarthritic changes are seen radiographically as disk or joint space narrowing, subchondral sclerosis, and osteophytosis (Figure 47-3).

Imaging evidence of lumbar spondylosis is common in the general population, increases with age, and may be unrelated to back symptoms. Radiographic abnormalities such as single disk degeneration, facet joint degeneration, Schmorl's nodes, mild spondylolisthesis, and mild scoliosis are equally prevalent in persons with and without back pain.²² The situation is further complicated by the observation that patients with severe mechanical LBP may have

minimal radiographic changes, and conversely patients with advanced changes may be asymptomatic.

The clinical spectrum of mechanical LBP is wide. Patients may present with acute LBP (with recurrent attacks in some), whereas chronic LBP (often with periods of acute exacerbation) may develop in others. Somatic referral may lead to sclerotomal pain that radiates into the buttocks and lower extremities. Lumbar spondylosis predisposes patients to intervertebral disk herniation, spondylolisthesis, and spinal stenosis.

In some patients with facet joint osteoarthritis the pain may radiate into the buttock and posterior thigh, be alleviated with forward flexion, and be exacerbated by bending ipsilateral to the involved joint (facet syndrome).

The terms *internal disk disruption* and *diskogenic low back pain* are used interchangeably and remain controversial diagnoses.¹³ The disorder is diagnosed by provocative diskography. Following contrast injection into several disks in sequence, the radiographic appearance and induced pain at each level are assessed. If injection into a disk reproduces a patient's usual LBP, the test is considered positive. Advocates of this technique interpret a positive diskogram as defining the particular disk as the primary pain generator, and spinal fusion or disk arthroplasty is frequently recommended.² However, injection into a disk can simulate the quality and location of pain known not to originate from that disk.²³ Furthermore, diskographic abnormalities and induced pain are frequently seen in asymptomatic persons and, more importantly, the diskogenic pain attributed to disk disruption frequently improves spontaneously.^{8,11} Therefore the clinical importance and appropriate management of this condition remains unclear.

Focal high signal in the posterior annulus fibrosus as seen on T2-weighted MRI images, sometimes referred to as a

Figure 47-3 Lumbar spondylosis. Anteroposterior (A) and lateral (B) radiographs of the lumbar spine show the cardinal features of disk-space narrowing, marginal osteophytes, and end plate sclerosis. (Courtesy Dr. John Crues, University of California, San Diego.)

high-intensity zone, is believed to represent tears in the annulus fibrosus and to correlate with positive findings on provocative diskography.⁸ The high prevalence of high-intensity zones in asymptomatic individuals limits its clinical value.²⁴

Spinal instability is seen in some patients with lumbar spondylosis. It is identified by demonstrating abnormal vertebral motion (anteroposterior displacement or excessive angular change of adjacent vertebrae) on lateral radiographs in flexion and extension. However, such spinal motion may be seen in asymptomatic persons and its natural history and relationship to the causation of LBP is unclear. Thus the diagnosis of spinal instability (in the absence of fractures or spondylolisthesis) as a cause of LBP and its treatment by spinal fusion remains controversial.

Disk Herniation

Intervertebral disk herniation occurs when the nucleus pulposus in a degenerated disk prolapses and pushes out the weakened annulus, usually posterolaterally. Imaging evidence of disk herniation has a high prevalence in the general population with one study finding MRI evidence of disk herniation in 27% of asymptomatic individuals.²⁵ Occasionally, however, the herniated disk can cause nerve root impingement leading to lumbosacral radiculopathy (Figures 47-4 and 47-5). A herniated intervertebral disk is the most common cause of sciatica.⁸

The lumbosacral spine is susceptible to disk herniation because of its mobility. Seventy-five percent of flexion and extension occurs at the lumbosacral joint (L5-S1), and 20%

occurs at L4-5²⁶ (with more torsion at the L4-5 level). Probably related to this, 90% to 95% of clinically significant compressive radiculopathies occur at these two levels.¹¹

Disk herniation is rare in young individuals with the frequency increasing with age. The peak frequency of herniation at the L5-S1 and L4-L5 levels is between the ages of 44 and 50 with a progressive decline in frequency thereafter.²⁷

The genesis of sciatica is felt to have both a mechanical (disk material impinging on a nerve root) and biologic component. Inflammation, vascular invasion, immune responses, and an array of cytokines have been implicated.

Figure 47-4 Schematic drawing showing posterolateral disk herniation resulting in nerve root impingement.

(Courtesy Dr. John Crues, University of California, San Diego.)

The clinical features of disk herniation resulting in lumbosacral radiculopathy have already been discussed (see history, physical examination, and Figure 47-2). It should be noted that immediate imaging is unnecessary in patients without a clinically significant neurologic deficit and no red flags to suggest an underlying systemic pathology (see Table 47-1). L1 radiculopathy is rare and presents with symptoms of pain, paresthesias, and sensory loss in the inguinal region.²⁸ L2, L3, and L4 radiculopathies are uncommon and more likely to be seen in older patients with lumbar spinal stenosis.

The natural history of disk herniation is favorable with progressive improvement expected in most patients. Sequential MRI studies reveal that the herniated portion of the disk regresses with time and there is partial or complete resolution in two thirds of cases after 6 months.^{11,29} Only approximately 10% of patients have sufficient pain after 6 weeks of conservative care, and for this group decompressive surgery is considered.¹¹ Even a sequestered fragment (piece of herniated material that breaks off and is free in the epidural space) tends to be reabsorbed with time.³⁰

Rarely a large midline disk herniation, usually L4-5,⁹ compresses the cauda equina resulting in cauda equina syndrome. Patients usually present with LBP, bilateral radicular pain, and bilateral motor deficits with leg weakness. Physical examination findings are often asymmetric. Sensory loss in the perineum (saddle anesthesia) is common, and urinary retention with overflow incontinence is usually present.¹¹ Fecal incontinence may also occur. Other causes of cauda equina syndrome include neoplasia, epidural abscess, hematoma, and rarely lumbar spinal stenosis. Cauda equina syndrome is a surgical emergency because neurologic results are affected by the time to decompression.⁶

Spondylolisthesis

Spondylolisthesis is the anterior displacement of a vertebra on the one beneath it. There are two major types: isthmic and degenerative.

Isthmic spondylolisthesis (Figure 47-6) is caused by bilateral spondylolysis. Spondylolysis is a defect in the pars interarticularis that is most commonly seen at L5. It is typically a fatigue fracture acquired early in life that is more commonly seen in boys. Spondylolysis progresses to spondylolisthesis in approximately 15% of patients.³¹

Degenerative spondylolisthesis develops in some patients with severe degenerative changes with subluxation at the facet joints allowing anterior or posterior movement of one vertebra over another. It is usually seen in an older age group (typically older than age 60), is more common in women, and most frequently involves the L4-5 level.⁹

Most patients, especially those with a minor degree of spondylolisthesis, are asymptomatic. Some may complain of an aching mechanical LBP. Neurologic complications may occur in some with greater degrees of spondylolisthesis. Nerve root impingement is more likely to be seen in patients with isthmic spondylolisthesis (especially L5 nerve root), whereas in degenerative spondylolisthesis the more likely clinical presentation is of spinal stenosis. Rarely extreme slippage results in cauda equina syndrome. In view of its potential dynamic nature, spondylolisthesis may be missed if standing radiographs are not obtained.

Spinal Stenosis

Lumbar spinal stenosis is defined as a narrowing of the central spinal canal, its lateral recesses, and neural foramina that may result in a compression of lumbosacral nerve roots. Spinal stenosis can occur at one or multiple levels, and the

Figure 47-6 A, Spondylolysis with bilateral defects in the pars interarticularis (arrows). B, Spondylolysis of the L5 vertebra (arrow) resulting in isthmic spondylolisthesis at L5-S1.

narrowing may be asymmetric. It is important to recognize that 20% to 30% of asymptomatic adults older than age 60 have imaging evidence of spinal stenosis. The prevalence of symptomatic lumbar spinal stenosis is not established. It is, however, the most frequent indication for spinal surgery in patients older than age 65.

Congenital idiopathic spinal stenosis (Table 47-3) is not uncommon and results from congenitally short pedicles. These patients tend to become symptomatic early (third to fifth decade of life) when superimposed mild degenerative changes that would normally be tolerated result in sufficient further narrowing of the spinal canal to cause symptoms.³²

Degenerative changes are the cause of spinal stenosis in the vast majority of cases. The intervertebral disk loses

height as it degenerates. This results in a bulging or buckling of the now redundant and often hypertrophied ligamentum flavum into the posterior part of the canal. Any herniation of the degenerated disk narrows the anterior part of the canal while hypertrophied facets and osteophytes may compress nerve roots in the lateral recess or intervertebral foramen (Figures 47-7 and 47-8). Any degree of spondylolisthesis will further exacerbate spinal canal narrowing.

The hallmark of spinal stenosis is neurogenic claudication (pseudoclaudication). The symptoms of neurogenic claudication are usually bilateral but often asymmetric. The primary complaint is of pain in the buttocks, thighs, and legs. The pain may be accompanied by paresthesias. Neurogenic claudication is induced by standing erect or walking and relieved by sitting or flexing forward. This forward flexion increases the spinal canal dimensions and may lead to the patient adopting a simian stance. It is therefore not

(Courtesy Dr. John Crues, University of California, San Diego.)

surprising that these patients often feel relief by stooping forward while holding onto a shopping cart (the “shopping cart sign”) and may exhibit surprising endurance while pedaling a stationary bicycle. Symptoms of neurogenic claudication probably represent intermittent mechanical and ischemic disruption of lumbosacral nerve root function.³³ The patients also often have a sense of weakness in the lower extremities, and unsteadiness of gait is a frequent complaint. The finding of a wide-based gait in a patient with LBP has a more than 90% specificity for lumbar spinal stenosis.³⁴ Factors that favor a diagnosis of neurogenic claudication over vascular claudication include preservation of pedal pulses, provocation of symptoms by standing erect just as readily as by walking, relief of symptoms with flexion of the spine, and location of maximal discomfort to the thighs rather than the calves.

The physical examination of a patient with lumbar spinal stenosis is often unimpressive.⁶ Severe neurologic deficits are not commonly seen. Lumbar range of motion may be normal or reduced, and the result of straight leg-raising is usually negative. Deep tendon reflexes and vibration sense may be reduced. Mild weakness is seen in some. The significance of these findings is often difficult to determine in elderly patients. However, in a few patients with spinal stenosis a fixed nerve root injury may occur, resulting in a lumbosacral radiculopathy or rarely a cauda equina syndrome.

The diagnosis of lumbar spinal stenosis is most often suspected when a history of neurogenic claudication is elicited. The diagnosis is best confirmed by MRI.

Spinal stenosis is generally an indolent condition where the symptoms evolve gradually and the natural history is benign. In a study of patients with lumbar spinal stenosis followed for 49 months without surgical intervention,

symptoms remained unchanged in 70%, improved in 15%, and worsened in 15%.³⁵ As such, prophylactic surgical intervention is not warranted.³²

Diffuse Idiopathic Skeletal Hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is characterized by calcification and ossification of paraspinous ligaments and the entheses.³⁶ It is a noninflammatory condition of unknown etiology that is not associated with HLA-B27 positivity.

DISH has been associated with obesity, diabetes mellitus, and acromegaly.³⁷ It is rarely diagnosed before the age of 30, is more commonly seen in men, and the prevalence rises with age.³⁸

The thoracic spine is most commonly involved, although the cervical and lumbar regions may also be affected. Ossification of the anterior longitudinal ligament is best seen on a lateral radiograph of the thoracic spine. This together with bridging enthesophytes in the spine give the appearance of flowing wax on the anterior and right lateral aspects of the spine. Involvement of the left lateral aspect in patients with situs inversus has led to speculation that the descending aorta plays a role in the location of the calcification. Intervertebral disk spaces and facet joints are preserved (unless there is coexisting lumbar spondylosis) and the sacroiliac joints appear normal. This helps differentiate DISH from spondylosis and the spondyloarthritides. Almost any extra-spinal osseous or articular site may be affected.³⁹ Irregular new bone formation (“whiskering”) is often best seen at the iliac crests, ischial tuberosities, and femoral trochanters. Ossification of tendons and ligaments at sites of attachment (such as the patella, olecranon process, and calcaneus) and periarticular osteophytes (such as the lateral acetabulum

and inferior portion of the sacroiliac joint on pelvic radiographs) may also be seen. Severe ligamentous calcification may be seen in the sacrotuberous and iliolumbar ligaments and heterotopic bone formation following hip replacement in patients with DISH has been described.⁴⁰

DISH may be entirely asymptomatic. The most common complaint encountered is of pain and stiffness involving the spine, often the thoracic region. Usually there is only a moderate limitation of spinal motion. Extensive ossification of the anterior longitudinal ligament together with large anterior enthesophytes may occasionally compress the esophagus and cause dysphagia.³⁶ Ossification of the posterior longitudinal ligament is almost exclusively seen in the cervical spine and may occur either as a discrete disorder or as part of DISH. This can rarely lead to cervical myelopathy. Pain and tenderness may be present at the entheses, and these patients may have findings of lateral or medial humeral epicondylitis, Achilles tendinitis, or plantar fasciitis.

If treatment of DISH is necessary at all, it is symptomatic. Most patients respond to acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and judicious use of glucocorticoid injections for painful enthesopathy.

Nonspecific Low Back Pain

This is also referred to as *idiopathic LBP*. As mentioned earlier, a precise pathoanatomic diagnosis, with identification of the pain generator, cannot be made in up to 85% of the patients. This is largely because of the nonspecific nature of the symptoms in patients with LBP and the weak association of these symptoms with findings on imaging. Thus terms such as lumbago, strain, and sprain have come into use. Strain and sprain have never been histologically characterized. Therefore nonspecific LBP is a more accurate label for these patients who have a mostly self-limited syndrome of acute mechanical LBP. The severity of pain can vary from mild to severe, and whereas sometimes the back pain develops immediately after a traumatic event such as lifting a heavy object or a twisting injury, other patients may just wake up with LBP. Most patients are better within 1 to 4 weeks³ but remain susceptible to similar future episodes. Less than 10% of patients develop chronic nonspecific LBP.

Neoplasm

Neoplasms are an uncommon, but nevertheless important, cause of LBP. In a primary care setting, neoplasia accounts for less than 1% of the patients with LBP.¹¹

In a large prospective study of patients in a walk-in clinic, a history of cancer, unexplained weight loss, failure to improve after 1 month of conservative therapy, and age older than 50 years were each associated with a higher likelihood for cancer.⁴¹ By far the most important predictor for the likelihood of underlying cancer as the cause of LBP was a prior history of cancer.

The typical patient with LBP secondary to spinal malignancy presents with a persistent and progressive pain that is not alleviated by rest and indeed is often worse at night. In some patients a spinal mass can result in a lumbosacral radiculopathy or cauda equina syndrome. Acute LBP

may be the presentation in a patient with a pathologic compression fracture. Rarely, leptomeningeal carcinomatosis (in patients with breast cancer, lung cancer, lymphoma, or leukemia) may present with a lumbosacral polyradiculopathy.⁴²

Most cases result from involvement of the spine by metastatic carcinoma⁴ (especially prostate, lung, breast, thyroid, or kidney) or multiple myeloma. Metastatic vertebral lesions, more commonly seen in the thoracic spine, account for 39% of bony metastases in patients with primary neoplasms.⁴³ Spinal cord tumors, primary vertebral tumors, and retroperitoneal tumors may rarely be the cause of LBP.¹¹

Osteoid osteoma, a benign tumor of bone, typically presents with LBP in the second or third decade of life. The pain is often accompanied by a functional scoliosis secondary to paravertebral spasm. Patients may present with pain even before the osteoid osteoma is visible radiographically. Osteoid osteomas predominantly involve the posterior elements of the spine, usually the neural arch. A sclerotic lesion measuring less than 1.5 cm with a lucent nidus is pathognomonic.⁴⁴ A bone scan, CT scan, or MRI should be ordered if an osteoid osteoma is suspected but not detected on radiography.

Plain radiographs are less sensitive than other imaging tests in detecting neoplastic lesions because approximately 50% of trabecular bone must be lost before a lytic lesion is visible.⁸ Metastatic lesions may be lytic (radiolucent), blastic (radiodense), or mixed. The majority of metastases are osteolytic. Vertebral bodies are primarily involved because of their rich blood supply associated with red marrow, and unlike infections the disk space is usually spared. It should be noted that a purely lytic lesion such as multiple myeloma will not be detected by a bone scan. MRI offers the greatest sensitivity and specificity in the evaluation of spinal tumors and is generally the modality of choice.

Infection

Vertebral osteomyelitis (spinal osteomyelitis, spondylodiskitis) may be acute (usually pyogenic) or chronic (pyogenic, fungal, or granulomatous). Acute vertebral osteomyelitis evolves over a period of a few days or weeks and is the major focus of this discussion.

Vertebral osteomyelitis usually results from hematogenous seeding, direct inoculation at the time of spinal surgery, or contiguous spread from an infection in the adjacent soft tissue. The lumbar spine is the most common site of vertebral osteomyelitis followed by the thoracic and cervical spine.⁴⁵ *Staphylococcus aureus* is the most common microorganism followed by *Escherichia coli*. Coagulase-negative staphylococci and *Propionibacterium acnes* are almost always the cause of exogenous osteomyelitis after spinal surgery, particularly if internal fixation devices are used.⁴⁵

A source of infection is detected in about half the cases with endocarditis diagnosed in up to a third of cases of vertebral osteomyelitis.⁴⁵ Other common sites for the primary focus of infection are the urinary tract, skin, soft tissue, a site of vascular access, bursitis, or septic arthritis.⁴⁶ Most patients with hematogenous pyogenic vertebral osteomyelitis have underlying medical disorders such as diabetes, coronary artery disease, immunosuppressive disorders,

malignancy, and renal failure.^{45,46} Intravenous drug abuse is also a risk factor for vertebral osteomyelitis.

Vertebral osteomyelitis may be complicated by an epidural or paravertebral abscess. This may result in neurologic complication.

Back pain is the initial symptom in most patients. The pain tends to be persistent, present at rest, exacerbated by activity, and at times well localized. Point tenderness on percussion over the spine has sensitivity but not specificity for vertebral osteomyelitis. Fever is present in only about half of the patients,⁴⁵ partly because most patients are using analgesic medications. Because most cases of vertebral osteomyelitis result from hematogenous seeding, the dominant manifestations initially may be of the primary infection. An epidural abscess may result in a radiculopathy or cauda equina syndrome.

Leukocytosis is seen in only about two-thirds of the patients. However, almost all the patients have increases in the erythrocyte sedimentation rate and C-reactive protein, with the latter best correlating with clinical response to therapy.⁴⁶ If blood cultures are negative in a patient suspected of having vertebral osteomyelitis, a bone biopsy (CT-guided or open) with appropriate culture studies and histopathologic analysis is indicated.

Plain radiography is usually the initial imaging study. Radiographic changes, however, occur relatively late and are nonspecific. Typically there is loss of disk height and loss of cortical definition followed by bony lysis of adjacent vertebral bodies. MRI is the most sensitive and specific imaging technique to detect spinal infections. The classic finding of pyogenic osteomyelitis is involvement of two vertebral bodies with their intervening disk.⁸ In a patient with neurologic impairment, MRI should be done early to rule out an epidural abscess. Whenever possible, antimicrobial therapy should be directed against an identified susceptible pathogen. There are no data from randomized, controlled trials to guide decisions about specific antimicrobial regimens or the duration of therapy.⁴⁶ Intravenous therapy of at least 4 to 6 weeks, and possibly additional oral antibiotic therapy, is usually recommended. Surgery may be necessary to drain an abscess, although CT-guided catheter drainage may be sufficient in some cases. Surgical débridement is always required when infection is associated with a spinal implant with removal of the implant whenever possible.⁴⁶

Tuberculosis and nontubercular granulomatous infections (blastomycosis, cryptococcosis, actinomycosis, coccidioidomycosis, and brucellosis) of the spine should be considered in the appropriate clinical and geographic setting.

Lumbar nerve roots are commonly involved in patients with herpes zoster. In most cases a single unilateral dermatome is involved. Pain is often severe and may precede the appearance of a maculopapular rash that evolves into vesicles and pustules.

Inflammation

The spondyloarthritides cause inflammatory LBP (see [Table 47-1](#)) and are discussed in detail elsewhere (see [Chapters 74 to 78](#)).

Metabolic Disease

The major consideration in this category is the occurrence of acute mechanical LBP secondary to a vertebral compression fracture in a patient with osteoporosis ([Chapter 101](#)). Most patients are postmenopausal women.

Paget's disease of bone ([Chapter 101](#)) is most often detected in an asymptomatic patient by the incidental finding of either an elevated alkaline phosphatase or characteristic radiographic abnormality. The spine is the second most commonly affected site after the pelvis. Within the spine the L4 and L5 vertebrae are most commonly involved.⁴⁷ Paget's disease of the spine may involve single or multiple levels. The vertebral body is almost always involved together with a variable portion of the neural arch. Radiographically Paget's disease is seen as areas of enlargement of the bone with thickened, coarsened trabeculae. Usually a mixed picture of sclerotic and lytic Paget's disease is encountered. The vertebrae may enlarge, weaken, and fracture. LBP may occur due to the pagetic process itself (with periosteal stretching and vascular engorgement), microfractures, overt fractures, secondary osteoarthritis of the facet joints, spondylolysis with or without spondylolisthesis, or sarcomatous transformation (rare).⁴⁷ Neurologic complications secondary to Paget's disease of the lumbar spine include sciatica secondary to nerve root impingement, spinal stenosis, and rarely a cauda equina syndrome.

Visceral Pathology

Disease in organs that share segmental innervation with the spine can cause pain to be referred to the spine. In general, pelvic diseases refer pain to the sacral area, lower abdominal diseases to the lumbar area, and upper abdominal diseases to the lower thoracic spine area. Local signs of disease such as tenderness to palpation, paravertebral muscle spasm, and increased pain on spinal motion are absent.

Vascular, gastrointestinal, urogenital, or retroperitoneal pathology may on occasion cause LBP. A partial list of causes includes an expanding aortic aneurysm, pyelonephritis, ureteral obstruction due to renal stones, chronic prostatitis, endometriosis, ovarian cysts, inflammatory bowel disorders, colonic neoplasms, and retroperitoneal hemorrhage (usually in a patient taking anticoagulants).

Most abdominal aortic aneurysms are asymptomatic but may become painful as they expand. Aneurysmal pain is usually a harbinger of rupture. Rarely the aneurysm may develop leakage. This produces severe pain with abdominal tenderness. Most patients with aortic dissection present with a sudden onset of severe "tearing" pain in the chest or upper back. Pain originating from a hollow viscus such as the ureter or colon is often colicky.

Miscellaneous

LBP may be part of the clinical spectrum in innumerable conditions. It would not be practical or useful to discuss these entities here. Considered next are some of the more important or controversial causes of LBP.

The piriformis syndrome is felt to be an entrapment neuropathy of the sciatic nerve related to anatomic variations in the muscle-nerve relationship or to overuse. The

piriformis is a narrow muscle that originates from the anterior part of the sacrum and inserts into the greater trochanter. It is an external rotator of the hip. There is, however, debate about the existence of the piriformis syndrome as a discrete entity because of the lack of objective, validated, and standardized tests. The diagnosis is clinical. Patients complain of pain and paresthesias in the gluteal region that radiate down the leg to the foot. Unlike sciatica from lumbosacral nerve root compression, the pain is not restricted to a specific dermatome. The straight leg-raising test is usually negative. There may be tenderness over the sciatic notch. Physical examination maneuvers for the diagnosis of piriformis syndrome are based on the notion that stretching the irritated piriformis muscle may provoke sciatic nerve compression. This can be done by internally rotating the hip (Freiburg's sign) or by flexion, adduction, and internal rotation (FAIR maneuver) of the hip. Physical therapy that focuses on stretching the piriformis muscle and NSAIDs are generally the treatments offered.

Sacroiliac joint dysfunction is a controversial diagnosis. It is a term used to describe pain in the sacroiliac region related to abnormal sacroiliac joint movement or alignment. However, tests of pelvic symmetry or sacroiliac joint movement have low intertester reliability and fluoroscopically guided sacroiliac joint injections have been unreliable in diagnosis and treatment.^{48,49} Radiographic degenerative changes of the sacroiliac joint are often noted in the evaluation of patients with LBP. It remains unresolved as to whether these changes are the primary cause of the back pain.⁵⁰

Lumbosacral transitional vertebrae include sacralization of the lowest lumbar vertebral body and lumbarization of the uppermost sacral segment. The association of these variants with LBP remains controversial.

A "back mouse" is a mobile subcutaneous fibro-fatty nodule in the lumbosacral area. The nodule may be tender. Although there are case reports,⁵¹ the association with LBP remains unproven.

Epidural lipomatosis may be seen in obese patients, but it is more commonly seen as a rare side effect of long-term use of corticosteroids. There is an increase in epidural adipose tissue that causes a narrowing of the spinal canal. This is usually an incidental finding, although it may lead to compression of neural structures.

LBP during pregnancy is common. The pain usually starts between the fifth and seventh months of pregnancy.⁵² The etiology of LBP in pregnancy is unclear. Biomechanical, hormonal, and vascular factors have been implicated. Most women have resolution of their pain postpartum.

Fibromyalgia (see Chapter 52) and polymyalgia rheumatica (see Chapter 88) are two frequently encountered rheumatologic conditions in which LBP may be a prominent part of the clinical syndrome.

TREATMENT

Specific treatment is available only for the small fraction of patients with LBP who have either evidence of clinically significant neural compression or an underlying systemic disease (cancer, infection, visceral disease, and spondyloarthritis). In the vast majority of patients with LBP, either the precise pathoanatomic cause (i.e., the pain generator)

cannot be determined or, when the cause is determined, no specific treatment is available. These patients are managed with a conservative program centered on analgesia, education, and physical therapy. The goal of treatment is relief of pain and restoration of function. Surgery is rarely necessary (Figure 47-9).

One should be wary of the proliferation of unproven medical, surgical, and alternative therapies. Most have not been rigorously tested in well-designed randomized controlled trials. Uncontrolled studies can produce a misleading impression of efficacy due to fluctuating symptoms and the largely favorable natural history of LBP in most patients.

For management purposes, patients with LBP are considered to have either acute LBP (duration <3 months), chronic LBP (duration >3 months), or a nerve root compression syndrome.

Acute Low Back Pain

The typical patient seeks medical attention for sudden onset of severe mechanical LBP. Examination usually reveals paravertebral muscle spasm, often resulting in loss of the normally present lumbar lordosis and severe decrease in range of motion secondary to pain. The prognosis for acute LBP is excellent. Indeed, only about a third of these patients seek medical care and more than 90% recover within 8 weeks or earlier.⁵³

Patients with acute LBP are advised to stay active and continue ordinary daily activities within the limits permitted by pain. This leads to more rapid recovery than bed rest.⁵⁴ Bed rest of more than 1 or 2 days is discouraged.

Pharmacologic therapy is used for symptomatic relief. Unfortunately, no medication has consistently been shown to result in large average benefits on pain and evidence of beneficial effects on function is even more limited.⁵ Acetaminophen and NSAIDs are first-line options for analgesia. Short-term use of opioids is reasonable in patients with severe disabling LBP or in those at high risk of complications due to NSAIDs. For patients with acute LBP, short-acting opioids are generally recommended. Muscle relaxants are moderately effective for short-term symptomatic relief but have a high prevalence of adverse effects including drowsiness and dizziness.⁵ It is unclear whether these medications truly relax muscles or their effects are related more to sedation or other nonspecific effects. Benzodiazepines have similar efficacy to muscle relaxants for short-term pain relief but are associated with risks for abuse, addiction, and tolerance.¹⁸

Back exercises are not helpful in the acute phase, and a physical therapy referral is usually unnecessary in the first month. Later an individually tailored program that focuses on core strengthening, stretching exercises, aerobic conditioning, functional restoration, and loss of excess weight is recommended to prevent recurrences.^{6,11} The purpose of back exercises is to stabilize the spine by strengthening trunk muscles. Flexion exercises strengthen the abdominal muscles, and extension exercises strengthen the paraspinal muscles. Numerous exercise programs have been developed and appear to be equally effective.

Patient education including use of education booklets is strongly recommended.¹⁸ The information provided should include causes of LBP, basic anatomy, favorable natural

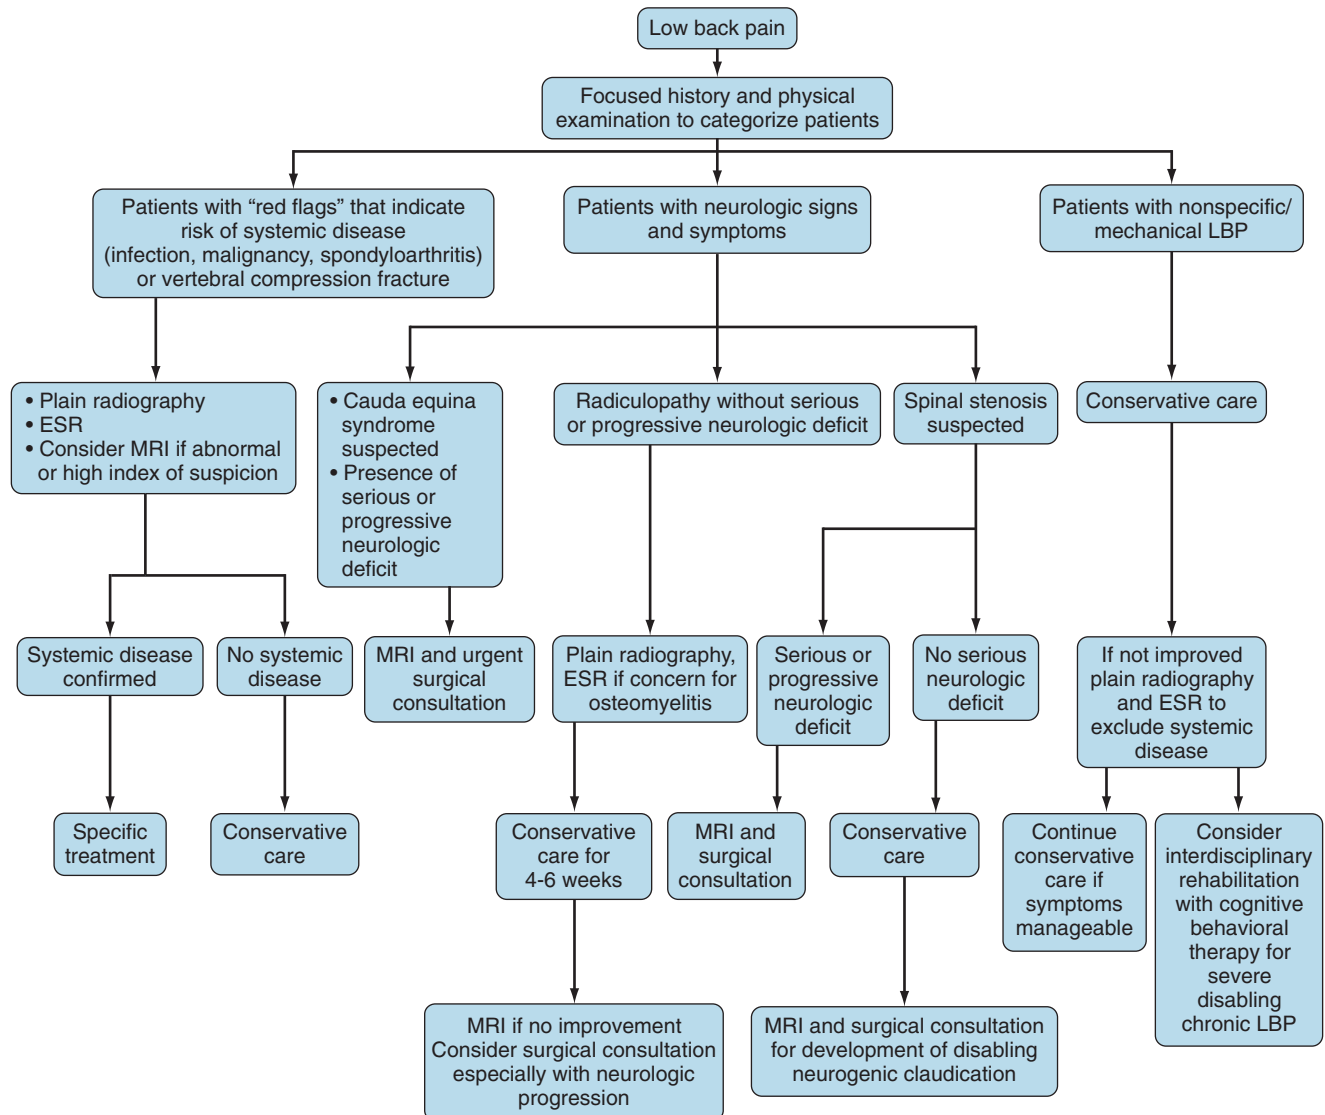

Figure 47-9 Algorithm for the differential diagnosis and treatment of low back pain. ESR, erythrocyte sedimentation rate; LBP, low back pain; MRI, magnetic resonance imaging.

history, minimal value of diagnostic testing, importance of remaining active, effective self-care options, and coping techniques.

Spinal manipulation is provided mainly by chiropractors and osteopaths. It may involve low-velocity mobilization or manipulation with a high-velocity thrust that stretches spinal structures beyond the normal range and is frequently accompanied by a cracking or popping sound. For acute LBP, current evidence suggests that manipulative therapy is no more effective than conventional medical therapy.¹⁸ There is no evidence that ongoing manipulation reduces the risk of recurrence of LBP.⁵⁵ There is insufficient evidence regarding the efficacy of massage and acupuncture in the treatment of acute LBP.¹⁸

Application of heat by heating pads or blankets is a reasonable self-care option for short-term relief of acute LBP. There is, however, insufficient evidence to recommend application of cold packs or the use of corsets and braces.¹⁸ Traction provides no significant benefit for LBP patients with or without sciatica.⁵⁶

Injection therapy is used mostly in subacute (>6 weeks) and chronic LBP. Epidural corticosteroid injections have gained remarkable, but unjustified, popularity. The rationale for their use is that the genesis of radicular pain, when a herniated disk impinges on a nerve root, is at least partly related to locally induced inflammation. Indeed, there is evidence of moderate benefit compared with placebo injection for short-term relief of leg pain in patients with radiculopathy due to a herniated nucleus pulposus.⁵⁷ However, epidural corticosteroid injections offer no significant functional benefit, nor do they reduce the need for surgery. It is important to note that there is no evidence for the effectiveness of epidural corticosteroid injections in LBP patients without radiculopathy.

A variety of other injection therapies using glucocorticoids or anesthetic agents, often in combination, are used in individuals with LBP with or without radicular pain and other symptoms in the leg. These include injection of trigger points, ligaments, sacroiliac joints, facet joints, and intradiscal steroid injections. There is no convincing evidence of

the efficacy of these interventions.^{58,59} Medial branch block for presumed facet joint pain and nerve root blocks for therapeutic or diagnostic purposes are also not recommended.⁵⁹ Unfortunately these invasive and expensive procedures are commonly used in interventional pain clinics.

A number of physical therapy modalities are currently used in the treatment of patients with subacute and chronic LBP. These include transcutaneous electrical nerve stimulation (TENS), percutaneous electrical nerve stimulation, interferential therapy, low-level laser therapy, shortwave diathermy, and ultrasound. There is insufficient evidence of efficacy to recommend their use.

Vertebral compression fractures secondary to osteoporosis are common. There is resolution of pain with fracture healing within a few weeks in most patients. Vertebroplasty and balloon kyphoplasty are two increasingly popular, invasive, and expensive procedures that are being used for the treatment of persistent pain associated with these fractures. Both procedures involve the percutaneous placement of needles into the vertebral body through or lateral to the pedicles, as well as the injection of bone cement to stabilize the fracture. Kyphoplasty differs from vertebroplasty in that the cement is injected into a void in the vertebral body created by inflation of a balloon. Several early studies had suggested a positive treatment effect for vertebroplasty.⁶⁰ However, two blinded, randomized, placebo-controlled trials of vertebroplasty for painful osteoporotic spinal fractures found no beneficial effect of vertebroplasty as compared with a sham procedure.^{61,62} Therefore on the basis of current evidence, the routine use of vertebroplasty or indeed kyphoplasty for relief of pain from osteoporotic compression fractures cannot be justified.

Chronic Low Back Pain

The clinical spectrum in patients with chronic LBP is wide. Some complain of severe, unrelenting pain, but most have a nagging mechanical LBP that may radiate into the buttocks and upper thighs. Patients with chronic LBP may experience periods of acute exacerbation. These exacerbations are managed according to the principles discussed earlier. A significant number of patients with chronic LBP remain functional and continue working, but overall the results of treatment are unsatisfactory and complete relief of pain is unrealistic for most. Patients with chronic LBP are largely responsible for the high costs associated with LBP. It is therefore incumbent on physicians who treat these patients to judiciously use proven therapies.

For most patients, first-line medication options are acetaminophen or NSAIDs. They may provide some degree of analgesia, but the evidence for their long-term efficacy is not compelling. Opioid analgesics or tramadol are an option when used judiciously in patients with severe disabling pain. Because of substantial risks including aberrant drug-related behaviors with long-term use in patients vulnerable to abuse or addiction, potential benefits and harms of opioid analgesics should be carefully weighed before starting therapy.^{18,63} There is no evidence that long-acting, around-the-clock dosing is more effective than short-acting or as-needed dosing, and continuous exposure to opioids could induce tolerance and lead to dose escalations.⁵ Muscle relaxants are not recommended for long-term use in patients with chronic

stable LBP. Antidepressants that inhibit norepinephrine uptake are thought to have pain-modulating properties independent of their effects on depression. As such, low-dose tricyclic antidepressants are an option for chronic LBP, although the treatment effect is small and adverse side effects are common.⁵ There is no evidence of efficacy of selective serotonin reuptake inhibitors for LBP. Depression is, however, common in patients with chronic LBP and should be treated appropriately. Duloxetine, a serotonin-norepinephrine reuptake inhibitor, may have marginal efficacy in patients with chronic LBP.^{64,65} There is insufficient evidence to recommend antiepileptic medications such as gabapentin and topiramate for pain relief in patients with LBP with or without radiculopathy.⁵

An individually tailored physical therapy program and patient education, as discussed in the section earlier on the treatment of acute LBP, are particularly important aspects in the management of a patient with chronic LBP. The use of physical therapy modalities and injection techniques (as discussed earlier) is not recommended for patients with chronic LBP. Lumbar supports and traction are ineffective. For most patients with LBP a medium-firm mattress or a back-conforming mattress (waterbed or foam) may be superior to a firm mattress.^{66,67}

A number of physical treatments have been used in treating chronic LBP. Spinal manipulation has been shown to be superior to sham manipulation but is no more effective than conservative medical therapy.⁶⁸ There is less evidence for the efficacy of massage and acupuncture.⁶⁸

There has been a proliferation of nonsurgical interventional therapies for back pain. Chemonucleolysis is used for the treatment of herniated disks with intradiskal injections of chymopapain (extracted from papaya). Chymopapain enzymatically digests the nucleus pulposus while leaving the annulus fibrosus intact. Potentially life-threatening anaphylactic reactions have occurred rarely. Chemonucleolysis has lost favor in the United States but remains popular in Europe. Radiofrequency denervation has most commonly been used for the treatment of presumed facet joint pain by targeting the medial branch of the primary dorsal ramus. It involves fluoroscopic placement of an electrode near the nerve and application of heat by using a radiofrequency current to coagulate the nerve. There is a lack of convincing evidence about the effectiveness of this invasive procedure.⁵⁸ Intradiskal electrothermal therapy (IDET) and percutaneous intradiskal radiofrequency thermocoagulation (PIRFT) involve placement of an electrode into the intervertebral disk of patients with presumed diskogenic pain and using electric or radiofrequency current to provide heat to thermocoagulate and shrink intradiskal tissue and destroy nerves. Current evidence does not support the use of IDET or PIRFT.^{58,69} Prolotherapy (also referred to as *sclerotherapy*) involves repeated injections of an irritant sclerosing agent into ligaments and tendinous attachments. It is based on the hypothesis that back pain in some patients stems from weakened ligaments and repeated injections of a sclerosing agent will strengthen the ligaments and reduce pain. On the basis of trial data, a guideline from the American Pain Society recommends against prolotherapy for chronic LBP.⁵⁸

Spinal cord stimulation is a procedure involving the placement of electrodes, percutaneously or by laminectomy, in the epidural space adjacent to the area of the

spine presumed to be the source of pain and applying an electric current in order to achieve sympatholytic and other neuromodulatory effects.⁵⁸ Power for the spinal cord stimulator is supplied by an implanted battery. Spinal cord stimulation is associated with a greater likelihood for pain relief compared with reoperation or conventional medical management in patients with failed back surgery syndrome with persistent radiculopathy.⁵⁸ At present there is no good evidence for the use of spinal cord stimulation for chronic LBP not related to the failed back surgery or failed back surgery syndrome without radiculopathy. Approximately a third of the patients involved in studies have experienced a complication following spinal cord stimulation implantation including electrode migration, infection, wound breakdown, and lead- and generator pocket-related complications.⁵⁸

Intraspinal drug infusion systems, using a subcutaneously implanted pump with attached catheter, have been used in some patients with chronic intractable LBP for the intrathecal delivery of analgesics, usually morphine. Adequate evidence to support this intervention is not available.

Chronic LBP is a complex condition that involves biologic, psychologic, and environmental factors. For patients with persistent and disabling nonradicular LBP despite recommended noninterdisciplinary therapies, the clinician should strongly consider intensive interdisciplinary rehabilitation with an emphasis on cognitive-behavioral therapy.⁵⁹ Interdisciplinary rehabilitation (also called *multidisciplinary therapy*) is an intervention that combines and coordinates physical, vocational, and behavioral components and is provided by multiple health professionals with different clinical backgrounds. Cognitive-behavioral therapy is a psychotherapeutic intervention that involves working with cognitions to change emotions, thoughts, and behaviors. There is strong evidence of improved function and moderate evidence of pain improvement with intensive interdisciplinary rehabilitation programs.²³ Functional restoration (also called *work hardening*) is an intervention that involves simulated or actual work in a supervised environment in order to enhance job performance skills and improve strength, endurance, flexibility, and cardiovascular fitness in injured workers. When combined with a cognitive-behavioral component, functional restoration is more effective than standard care alone for reducing time lost from work.⁶⁸

As previously discussed, the precise identification of the pain generator in an LBP patient with degenerative changes involving the lumbar spine and no radicular pain is usually not possible in contradistinction to the patient with radicular symptoms. It is therefore not surprising that as a general rule the results of back surgery are disappointing when the goal is relief of back pain rather than relief of radicular symptoms resulting from neurologic compression. As such, the role of surgical treatment for chronic disabling LBP without neurologic involvement in patients with degenerative disease remains controversial. The most common surgery performed is spinal fusion. Interbody fusion is achieved from either a posterior or an anterior approach or both combined for a circumferential fusion. All fusion techniques involve placement of a bone graft between the vertebrae. Instrumentation refers to the use of hardware such as screws, plates, or cages that serve as an internal splint

while the bone graft heals. Bone morphogenetic proteins are sometimes used to speed fusion. The rationale for fusion is based on its successful use at painful peripheral joints.

The current evidence is that for nonradicular back pain with degenerative changes, fusion is no more effective than intensive interdisciplinary rehabilitation but is associated with small to moderate benefits compared with standard nonsurgical care.⁷⁰ Furthermore, the majority of patients who undergo surgery do not experience an optimal outcome defined as no pain, discontinuation or occasional pain medication use, and return of high-level function.⁵⁹

Lumbar disk replacement using a prosthetic disk is a newer alternative to fusion. Disk replacement is approved in the United States for patients with disease limited to one disk between L3-S1 and no spondylolisthesis or neurologic deficit. No data support the hypothetical advantage that, unlike spinal fusion, prosthetic disks will protect adjacent levels from further degeneration by preserving motion. At present there is insufficient evidence regarding long-term benefits and harms of disk replacement to support recommendations.

Nerve Root Compression Syndromes

Disk Herniation

Patients with a herniated disk with radicular pain secondary to nerve root compression should be treated nonsurgically, as described in the section on acute LBP unless they have a serious or progressive neurologic deficit. Only about 10% of patients have sufficient pain after 6 weeks of conservative care that surgery is considered.¹¹ A decision to continue with nonsurgical therapy beyond 6 weeks in these patients does not increase risk for paralysis or cauda equina syndrome.⁵⁹ Surgery in these patients is associated with moderate short-term (through 6 to 12 weeks) benefits compared with nonsurgical therapy, though differences in outcome diminish with time and are generally no longer present after 1 to 2 years.^{56,59}

Open discectomy or microdiscectomy is the usual surgery performed on patients with serious or progressive neurologic deficit or electively on patients with persistent disabling pain secondary to radiculopathy (Table 47-4). Open discectomy generally involves a laminectomy, whereas microdiscectomy, using a smaller incision and an operating microscope, involves a hemilaminectomy to remove the disk fragment compressing the nerve root. There are no

Table 47-4 Indications for Surgical Referral

Disk Herniation
Cauda equina syndrome (emergency)
Serious neurologic deficit
Progressive neurologic deficit
Greater than 6 weeks of disabling radiculopathy (elective)
Spinal Stenosis
Serious neurologic deficit
Progressive neurologic deficit
Persistent and disabling pseudoclaudication (elective)
Spondylolisthesis
Serious or progressive neurologic deficit

clear differences in the outcome between open discectomy and microdiscectomy. There is insufficient evidence to evaluate the efficacy of sequestrectomy, or various laser-assisted, endoscopic, percutaneous, and other minimally invasive methods.^{70,71}

Epidural corticosteroid injections may offer moderate benefit for short-term relief of radicular pain but do not offer significant functional benefit and do not reduce the need for surgery.⁵⁷

Anti-tumor necrosis factor therapy is under investigation in patients with lumbar radiculopathy. A small randomized controlled trial with addition of a short course of adalimumab to the treatment regimen of patients with severe and acute sciatica resulted in a small decrease in leg pain and fewer surgical procedures.⁷² However, another randomized controlled trial found no difference between infliximab and a saline infusion.⁷³

Spinal Stenosis

It is critical to understand the natural history of degenerative lumbar spinal stenosis before making treatment decisions. The symptoms of spinal stenosis remain stable for years in most patients and may improve in some. Dramatic improvement is uncommon. Even when symptoms progress, there is little likelihood of rapid deterioration of neurologic function. Therefore conservative nonoperative treatment is a rational choice for most patients.

There is a paucity of good data to guide the conservative management of lumbar spinal stenosis. Physical therapy is the mainstay of management, but evidence for the efficacy of specific standardized regimens is not available. Most regimens include core strengthening, stretching, aerobic conditioning, loss of excess weight, and patient education. Exercises that involve lumbar flexion such as bicycling are better tolerated. Strengthening of abdominal muscles may be helpful by promoting lumbar flexion and reducing lumbar lordosis. Lumbar corsets that maintain slight flexion may provide symptomatic relief. They should only be used for a limited number of hours a day to avoid atrophy of paraspinal muscles.

Acetaminophen, NSAIDs, and mild narcotic analgesics are used for symptomatic relief of pain.

Lumbar epidural corticosteroid injections are used on the assumption that symptoms may result from inflammation at the interface between the nerve root and compressing tissues.³² A small randomized controlled trial showed a reduction in pain and improvement in function at 6 months following use of epidural steroid injections.⁷⁴ However, observational data suggest that epidural injections do not influence functional status or the need for surgery at 1 year.⁷⁵

Surgery is indicated for the few patients with lumbar spinal stenosis who have a serious or progressive neurologic deficit. However, most surgery for lumbar spinal stenosis is elective. The indication for elective surgery is to relieve persistent and disabling symptoms of neurogenic claudication that have not responded to conservative care. In patients without fixed neurologic deficits, delayed surgery produces similar benefits to surgery selected as the initial treatment.^{32,76} The surgical goal is to decompress the central spinal canal and the neural foramina to eliminate pressure on the nerve roots. This is accomplished by laminectomy,

partial facetectomy of hypertrophied facet joints, and excision of the hypertrophied ligamentum flavum and any protruding disk material. Laminectomy with lumbar fusion should generally be reserved for patients who have spinal stenosis with spondylolisthesis. Unfortunately there is an alarming increase in spinal fusion surgery with routine use of complex fusion techniques in the absence of evidence of greater efficacy. The techniques include instrumentation, bone graft augmentation with bone cement and human bone morphogenetic proteins, and combined anterior and posterior fusion (often at multiple levels). These techniques are associated with increased perioperative mortality, major complications, rehospitalization, and cost.⁷⁷⁻⁷⁹

Overall, for patients with spinal stenosis, with or without spondylolisthesis, who have disabling symptoms of neurogenic claudication despite conservative care, there is some evidence supporting the effectiveness of decompressive laminectomy in reducing pain and improving function through 1 to 2 years.^{32,59,70} Beyond this time frame the benefits appear to diminish.

A less invasive alternative to decompressive laminectomy is the implantation of a titanium interspinous spacer at one or two vertebral levels. This spacer distracts adjacent spinous processes and thereby imposes lumbar flexion, which in turn potentially increases the spinal canal dimensions. There is preliminary evidence of efficacy in patients with one- or two-level spinal stenosis, without spondylolisthesis, and with a history of relief of neurogenic claudication with flexion.⁷⁰ There are no trials comparing the interspinous spacer with decompressive surgery.

Spondylolisthesis

The vast majority of patients with spondylolisthesis and chronic LBP are treated conservatively. Rarely a patient may need decompression surgery with fusion if a serious or progressive neurologic deficit develops from nerve root impingement or the patient develops disabling pseudoclaudication secondary to spinal stenosis. A randomized trial involving patients with isthmic spondylolisthesis and disabling isolated LBP or sciatica for at least a year suggested better results from fusion surgery than from nonsurgical care,⁸⁰ although the differences in outcome narrowed over a 5-year follow-up period.⁸¹

OUTCOME

The natural history of acute LBP is favorable. There is substantial improvement in pain and function within a month in the majority of patients,³ and more than 90% are better at 8 weeks.⁴ Only about a third of patients with acute LBP seek medical care. Presumably the rest improve on their own. Relapses that also tend to be brief are common and may affect up to 40% of patients within 6 months.

Improvement is also the norm for patients with sciatica secondary to a herniated disk.⁸² A third of these patients are significantly better in 2 weeks, and 75% improve after 3 months.⁸ Only about 10% of these patients ultimately undergo surgery.

The symptoms of spinal stenosis tend to remain stable in 70%, improved in 15%, and worsened in 15%.³⁵

The 7% to 10% of patients who develop chronic pain are largely responsible for the high costs associated with LBP and remain a major challenge. Factors that predict persistence of chronic disabling LBP include maladaptive pain coping behaviors, presence of nonorganic signs, functional impairment, poor general health status, psychiatric comorbidities, job dissatisfaction, disputed compensation claims, and a high level of “fear avoidance” (an exaggerated fear of pain leading to avoidance of beneficial activities).^{23,83}

SUMMARY

The outcome for most patients with LBP is good. The management of patients with chronic LBP, however, remains a challenge. The results of conservative and surgical management in these patients are unsatisfactory. There has been a proliferation and increasing utilization of a large number of expensive but unproven nonsurgical interventional techniques and physical therapy modalities.

Surgical intervention is indicated in the presence of a serious or progressive neurologic deficit. However, surgery in the absence of neurologic deficits, especially spinal fusion for degenerative changes, is controversial and not clearly effective. Rates of back surgery (including spinal fusion) in the United States are the highest in the world and continue to rise rapidly.⁷⁰ A particularly worrisome trend is the routine use of complex fusion techniques (with associated increased perioperative mortality, major complications, and cost) in the absence of evidence of greater efficacy.⁷⁷⁻⁷⁹ The use of sham surgery in controlled trials is controversial for ethical reasons. However, randomized trials incorporating a sham operation may be justifiable to test the efficacy of spinal fusion because the surgery is not performed for a life-threatening condition, the primary clinical outcomes are subjective, and the rate of complications is high.⁷⁹

An Australian study indicated that a television campaign advising people with back pain to stay active and keep working reduced work-injury claims and medical expenses and had a sustained effect of altering physicians' and patients' perceptions regarding back pain.⁸⁴ Perhaps public health initiatives may help prevent episodes of LBP from becoming chronic and disabling.²³

KEY POINTS

The clinician should be able to narrow the differential diagnosis of hip or knee pain down to two to three diagnoses after the history and physical examination.

Imaging studies should be used to confirm the diagnosis.

Conventional radiographs should usually be the initial imaging study ordered.

Many of the vital structures in the knee can be palpated easily or examined with provocative tests.

A knee effusion is often associated with internal derangement.

The clinician should suspect a torn meniscus if a patient has an effusion, joint line tenderness, and pain with hyperextension and hyperflexion.

Patients with osteoarthritis often complain of stiffness and pain with activity.

Inflammatory arthritis should be considered when a patient continues to experience pain despite resting the joint.

Groin pain with internal rotation of the hip is due to hip pathology until proven otherwise.

Concurrent hip and lumbosacral pathology is common.

It is estimated that musculoskeletal pain affects one-third to one-half of the general population.^{1,2} Disease is occurring as the baby boomers have reached middle age and beyond. This is exemplified by the increasing prevalence of hip and knee replacement operations, which rose by 16.2% to 884,400 procedures annually in the United States between 2002 and 2004.³ Furthermore, the prevalence of total knee and total hip arthroplasty is expected to double by 2016 and 2026, respectively.⁴ The hip and knee joints are two of the most commonly affected sites of musculoskeletal pain, with the prevalence of hip pain ranging from 8% to 30% in persons 60 years of age and older^{5,6} and the prevalence of knee pain ranging from 20% to 52% in persons 55 years of age or older. In general, women experience more musculoskeletal pain than men.⁷ There are also geographic and ethnic variations in the rates of both hip and knee pain. For example, there tends to be significantly less hip and knee pain with decreasing latitude, as well as significantly less hip pain and osteoarthritis in China than in the United States.⁸⁻¹⁵

When evaluating complaints of knee or hip pain, knowledge of the anatomy of these joints is necessary for formulating a differential diagnosis. Given the thin soft tissue

Hip and Knee Pain

JAMES I. HUDDLESTON • STUART GOODMAN

envelope around the knee and the fact that knee pain is rarely referred, the pain generators around the knee can often be elucidated with a complete history and thorough physical examination. Diagnosis of hip pain may be more challenging because the joint is deeper and the region is not infrequently the site of referred pain from the spine. An understanding of the basic biomechanics of these joints is also important in formulating a differential diagnosis because certain activities are likely to cause specific injuries.

This chapter focuses on the important aspects of the history, physical examination, and imaging modalities involved in evaluating patients with complaints of knee and hip pain. An appropriate, thorough workup of these patients will allow the clinician to formulate an accurate differential diagnosis in an efficient manner.

KNEE PAIN

History

A detailed history is perhaps the most important step in accurately diagnosing the cause of knee pain. Knee complaints generally fall into two broad categories, pain or instability. Pain may arise from injury to the articular surfaces (e.g., osteoarthritis, inflammatory arthritis, osteochondral defects, osteochondritis dissecans), torn menisci, quadriceps and patella tendon tears, bursitis, nerve damage, fractures, neoplasia, or infection. Referred pain from the hip or spine is less common. Instability is usually episodic and stems from injuries to the quadriceps-patellar extensor mechanism, collateral ligaments, or cruciate ligaments. It is important to distinguish true instability from the common complaint of “giving way” because the latter is usually due to a robust pain response rather than specific structural pathology.

Patients in certain age groups tend to experience similar injuries. In patients younger than 40 years, ligament injuries, acute meniscus tears, and patellofemoral problems are frequently encountered. In contrast, degenerative conditions such as osteoarthritis and degenerative meniscal lesions tend to occur more frequently in older patients.

The location and character of the pain are particularly important when evaluating knee pain because many of the structures vital to proper knee function are subcutaneous and can be palpated easily. We prefer to conceptualize the knee as three separate compartments—medial, lateral, and patellofemoral. Each compartment should be examined separately. The patient should be able to point to the exact area where the pain is most severe. The onset of the pain

should be determined. Osteoarthritis and inflammatory arthritis tend to have an insidious onset, whereas injuries to menisci and ligaments are usually associated with a traumatic event. Knowing the details of a traumatic event will be helpful. For example, a twisting injury, especially one sustained with a flexed knee, suggests a meniscus tear, whereas a noncontact knee injury associated with change of direction is more likely to produce a tear of the anterior cruciate ligament (ACL). Pain from degenerative arthritis tends to be associated with stiffness, is generally worse with ongoing activity during the day, and is exacerbated by exercise, stair climbing, getting up from a chair, getting in and out of a car, and so on.

The presence or absence of knee swelling is an important part of the history because knee effusions (fluid in the knee joint) usually accompany internal derangement. An effusion may also be present with synovitis, osteoarthritis, inflammatory arthritis, fractures, infection, and neoplasm. Distinguishing among soft tissue swelling around the knee, synovial thickening, and a true knee effusion is critical (see later). The timing or onset of the swelling is also important for determining the diagnosis. An acute cruciate or collateral ligament injury or osteochondral fracture will usually present with an acute hemarthrosis (occurring within an hour), whereas an effusion associated with arthritis tends to be more insidious in nature.

Complaints of “locking” are common. In a younger patient, locking may be due to a displaced meniscal tear. In older patients with degenerative arthritis, complaints of locking are often due to loose bodies. It is important to distinguish between true locking and diminished range of motion due to pain (so-called pseudolocking) because this distinction will determine which imaging studies are most appropriate.

Timing of the pain with activity is also important for making the correct diagnosis. Meniscus tears and ligament injuries leading to instability will be particularly troublesome with activities such as walking on uneven surfaces, stairs, and movements requiring knee flexion and pivoting. Osteoarthritis tends to be exacerbated by all load-bearing activities and relieved by rest.

The clinician should also explore the patient’s exercise tolerance and ability to perform activities of daily living. These details may give insight into the severity of the injury and will also guide treatment. Important details include the use of ambulatory assist devices (cane, crutches, walker, brace, and wheelchair), walking tolerance, and capability for other exercises (physical therapy).

A history of any previous treatments rendered should also be recorded. One’s response to physical therapy, analgesics, nonsteroidal anti-inflammatories, nutritional supplements (such as glucosamine and chondroitin), intra-articular injections of corticosteroids or hyaluronic acid derivatives, and any operative treatments will lend further insight into the accurate diagnosis and have implications for treatment once the diagnosis has been confirmed.

At the end of taking a detailed history, the clinician should be able to formulate a differential diagnosis with a short list of potential conditions. This information should then allow the physician to concentrate on specific aspects of a focused physical examination that will lead to confirmation of the diagnosis.

Physical Examination

General

After a brief overall assessment of the patient, the physical examination should begin with observation of the patient’s lower extremity coronal alignment and leg lengths. We prefer to have the patient stand with legs slightly apart while he or she faces the examiner (Figure 48-1). A goniometer is then used to measure the varus/valgus alignment of the knees. Evaluation of leg lengths should be performed with step blocks of known sizes. The total height of the blocks needed to make the iliac crests level with the floor is equivalent to the leg-length discrepancy (Figure 48-2).

Gait is examined next. Although a comprehensive discussion of gait analysis is beyond the scope of this chapter, all clinicians should routinely make a few basic observations when evaluating the patient with a knee problem. Antalgic gaits (shortened stance phase) and thrusts are commonly seen. Any disorder that causes lower extremity pain may cause an antalgic gait. Seen in the stance phase of gait, thrusts may be due to a progressive angular deformity secondary to degenerative changes or chronic ligamentous instability. Medial thrusts result from medial collateral ligament and/or posteromedial capsular laxity. Lateral thrusts arise from lateral collateral ligament or posterolateral corner laxity (Figure 48-3). Patients may also thrust into recurvatum (so called *back-knee deformity*) due to posterior capsular laxity or quadriceps weakness.

The patient should then transfer to the examination table for evaluation in a comfortable supine position. The examination should proceed with inspection and palpation before performing any provocative maneuvers. A pillow should be placed under the knee if full extension is not possible due to pain (e.g., fractures, displaced meniscus tears, large effusion). If there is no known pre-existing pathology, the contralateral knee can serve as an adequate control. The lower extremity should be inspected for any

Figure 48-1 Assessment of coronal alignment.

Figure 48-2 The total height of the blocks needed to make the iliac crests level is equal to the length discrepancy.

skin lesions, areas of ecchymosis, or surgical scars. Quadriceps atrophy should be noted, and a tape measure should be used to record thigh circumference. It is good practice to measure the thigh circumference at the same distance from the patella or joint line in each knee. The presence of an effusion should be noted. This will be seen as fullness or swelling in the suprapatellar pouch. The effusion should be confirmed by ballottement of the patella (Figure 48-4). Small effusions will require “milking” of the fluid upward into the suprapatellar pouch. This will allow for quantification of the amount of fluid (Figure 48-5). The active and

Figure 48-4 A-C, Large effusions can be detected by “ballotting” the patella with the knee in extension.

passive range of motion of both knees should be recorded with a goniometer.

The examiner should then proceed with palpation of all structures of the knee. It is important to do this in a systematic manner to ensure completeness. Palpation should be gentle but firm enough to detect subtle pathology. Structures to be palpated include the quadriceps tendon, the patella (superior and inferior poles), the pes anserinus bursa, the medial (Figure 48-6A) and lateral (Figure 48-6B) joint lines, the origins and insertions of the collateral ligaments, the tibial tubercle, and the popliteal fossa. Fullness in the posterior knee may be indicative of a Baker’s cyst.

Ligaments

Injuries to the collateral or cruciate ligaments may lead to knee instability. It is important to mention that for each

Figure 48-3 The femur shifts medially during a medial thrust (A) and laterally during a lateral thrust (B).

Figure 48-5 Small effusions can be appreciated by the “milking” of fluid into the suprapatellar pouch.

Figure 48-6 Palpation of the medial (A) and lateral (B) joint lines.

translational and rotational motion of the knee, there are both primary and secondary restraints. When a primary restraint is disrupted, motion will be limited by the secondary restraint. If a secondary restraint is injured and the primary restraint remains intact, then motion will not be abnormal. For example, the ACL is the primary restraint to anterior translation of the tibia, while the medial meniscus is the secondary restraint. ACL disruption will lead to a significant increase in anterior tibial translation. This translation will be increased if the patient had a prior medial meniscectomy.¹⁶

The collateral ligaments can be examined with stress applied in the coronal plane. They should be examined in full extension and in 30 degrees of flexion to remove the influence of the cruciate ligaments and the capsular restraints. With the patient in a supine position, a varus force is applied across the knee to test the lateral collateral ligament and a valgus force is applied across the knee to evaluate the medial collateral ligament.

The ACL is one of the most frequently injured structures in the knee. ACL insufficiency is also common in advanced osteoarthritis. Common mechanisms of injury include a direct blow to the lateral side of the knee (the “clipping” injury in football causing the triad of medial collateral ligament, ACL, and medial meniscus injuries¹⁷), as well as noncontact injuries that occur during cutting, pivoting, and

Figure 48-7 The anterior drawer test is performed by subluxating the tibia anteriorly with the knee in 90 degrees of flexion. The amount of anterior translation (mm) is noted. The end point is characterized as “soft” or “hard.”

jumping.¹⁸ Patients often report an audible “pop” accompanied by the acute onset of knee swelling. Multiple tests have been described to evaluate the ACL. The most sensitive tests for diagnosis of an ACL injury include the anterior drawer, Lachman,¹⁹ and pivot-shift tests.^{20,21} All three tests are performed with the patient in the supine position. The anterior drawer test is performed with the knee flexed to 90 degrees. The examiner places his or her hands on the posterior surface of the proximal tibia and subluxates the tibia anteriorly (Figure 48-7). Any gross movement of the tibia that is different from the contralateral side is considered abnormal. The Lachman test is performed with the knee in 30 degrees of flexion (to remove the contribution of secondary restraints). The examiner applies an anterior force on the tibia while stabilizing the femur with his or her contralateral hand. Any increase in anterior tibial translation relative to the contralateral side is considered abnormal (Figure 48-8). The pivot-shift test is performed with the knee in extension. The examiner holds the tibia in slight internal

Figure 48-8 The Lachman test is performed by applying an anterior force on the tibia while stabilizing the femur with the knee in 30 degrees of flexion.

Figure 48-9 A and B, The pivot-shift test is positive if the tibia reduces with a “clunk” or a “glide” at 20 to 40 degrees of flexion.

rotation and applies a valgus stress while the knee is slowly flexed. This combination of forces should cause the tibia to subluxate anteriorly if the ACL is injured. The test is positive if the tibia reduces with a “clunk” or a “glide” at 20 to 40 degrees of flexion (Figure 48-9).

The posterior cruciate ligament (PCL) is the strongest ligament in the knee,^{22,23} and thus injuries to the PCL are usually a result of significant knee trauma. The “dashboard” injury is a common mechanism for PCL injury and occurs during a motor vehicle accident when the flexed knee strikes the dashboard (Figure 48-10). The PCL can be evaluated with the posterior drawer, posterior sag, and quadriceps active tests. All tests are performed with the patient in the supine position. The posterior drawer test is performed

with the knee in 90 degrees of flexion. The examiner applies a posteriorly directed force to the tibia. Placement of one’s thumb tips at the anterior joint line will allow for quantification of any abnormal translation (Figure 48-11). The posterior sag test is positive when the tibia subluxates posteriorly with the knee at 90 degrees of flexion. Loss of the medial tibial step-off at the joint line should alert the examiner to a PCL injury (Figure 48-12).²² This test is usually positive in the chronic setting or under anesthesia in the acute setting. The quadriceps active test is performed with the knee in 60 degrees of flexion. The patient is asked to extend the knee while keeping his or her foot on the examination table. One will see reduction of the tibia in a positive test.²⁴

Figure 48-10 An injury to the posterior cruciate ligament can occur when the tibia strikes the dashboard, causing the tibia to subluxate posteriorly on the femur.

Figure 48-11 The posterior drawer test is performed by subluxating the tibia posteriorly with the knee in 90 degrees of flexion. The amount of posterior translation (mm) is noted. The end point is characterized as “soft” or “hard.”

Figure 48-12 The posterior sag test is positive when the tibia subluxates posteriorly with the knee at 90 degrees of flexion.

Injuries to the PCL are often accompanied by injuries to the posterolateral corner, a complex structure that functions as both a static and dynamic stabilizer of the knee.²³ It is composed of the lateral collateral ligament, the popliteofibular ligament, the popliteomeniscal attachment, the arcuate ligament, and the popliteus tendon and muscle.²⁵ Injuries to the posterolateral corner and/or the PCL can be examined with the “dial test” (Figure 48-13). The posterolateral corner structures restrain external rotation at 30 degrees of flexion, while the PCL restrains external rotation at 90 degrees of flexion. An increase of external rotation at 90 degrees of flexion without an increase in external rotation at 30 degrees of flexion suggests an isolated PCL injury. An increase of external rotation at 30 degrees of flexion without an increase at 90 degrees of flexion suggests an isolated injury to the posterolateral corner. Increased

external rotation at both 30 degrees and 90 degrees of flexion suggests combined PCL and posterolateral corner injuries.

Menisci

Traumatic and degenerative meniscal injuries are among the most common knee injuries. The menisci are considered the “shock-absorbing” cartilages of the knee. They also provide rotational and translational restraint. The medial meniscus tends to be more bean shaped and is both larger and less mobile than the lateral meniscus. The lateral meniscus tends to be more C shaped. These anatomic differences have implications for the different injury patterns seen in these two structures.

Meniscal tears usually occur with rotation of the flexed knee as it moves into extension. Tears of the medial meniscus are more common than tears of the lateral meniscus, likely due to the relative lack of mobility of the medial meniscus.²⁶ Patients will frequently complain of “locking” and “clicking” or of something “wrong” with the knee, and this usually results from displacement of the torn meniscus during motion. Common physical findings include pain with hyperflexion and with hyperextension, joint line tenderness, and an effusion. Many provocative tests have been described to diagnose meniscal tears. The McMurray²⁷ and Apley compression²⁸ tests are frequently performed, though they do lack sensitivity and specificity. The flexion McMurray test is performed with the patient supine and the hip and knee flexed to 90 degrees. A compressive and rotational force is applied to the knee as it is moved from a flexed to an extended position. The test is positive if the patient complains of pain (Figure 48-14). The Apley compression test is performed with the patient prone and the knee flexed to 90 degrees. In a positive test, the patient will complain of pain with rotation of the tibia. An arthroscopic

Figure 48-13 A and B, The degree of tibial external rotation is measured in the “dial” test.

Figure 48-14 A positive flexion McMurray test may indicate a torn meniscus.

photograph in [Figure 48-15](#) shows a tear in the posterior horn of the medial meniscus.

Quadriceps Tendon

Injuries to the quadriceps tendon are most common in the sixth and seventh decades of life. Patients with systemic lupus erythematosus, renal failure, endocrinopathies, diabetes, and various other systemic inflammatory and metabolic diseases tend to be at a higher risk for these injuries. The

Figure 48-15 Arthroscopic photograph of a tear in the posterior horn of the medial meniscus before (A) and after (B) debridement.

Figure 48-16 An extensor lag due to a complete tear in the quadriceps tendon.

prevalence of quadriceps tendon rupture after total knee arthroplasty is a rare (0.1%) but devastating complication.²⁹ Patients usually present with intense anterior knee pain after experiencing an eccentric quadriceps contraction during a fall or twisting injury. Physical examination reveals a palpable defect in the tendon, an effusion due to hemarthrosis, and hypermobility of the patella. Patients will usually not be able to fully extend their knee ([Figure 48-16](#)).

Patella Tendon

Problems with the infrapatellar tendon include tendinitis and rupture. Tendinitis is usually an overuse injury and is often associated with jumping, changes in activity level, and eccentric contractions during falls. Patients will exhibit tenderness at their tibial tubercle or at the inferior pole of their patella. Rupture of the patella tendon usually occurs in patients younger than 40 years of age and is associated with chronic patella tendinitis. Patients usually present with anterior knee pain and the inability to extend their knee.

Patellofemoral Pain

Anterior knee pain is a common complaint seen by many orthopedic surgeons. It is more common in women, and it accounts for up to 25% of all sports-related knee injuries.³⁰ A variety of factors contribute to the biomechanics of the patellofemoral joint and include overuse, the depth of the trochlea, the shape of the patella, quadriceps strength, the line of pull of the quadriceps relative to the patella tendon (the Q angle), the length of the patella tendon, the shape of the femoral condyles, and the articular cartilage. Abnormalities of any of these factors may contribute to this pain syndrome, and successful treatment is possible only with correct identification of any contributing factors.

Physical examination of the patellofemoral joint begins with an analysis of coronal alignment of the knee because any valgus deformity may contribute to lateral subluxation. The height of the patella relative to the tibial tubercle should be noted (patella alta or baja). The J sign is present when the patella slides laterally at terminal extension,

indicating excessive pull of the vastus lateralis. The vastus medialis obliquus is the primary stabilizer against lateral pull by the vastus lateralis. With the knee extended and the quadriceps relaxed, the examiner should make note of any patellar tilt. Any crepitus, either audible or palpable, should be noted as well. Crepitus is common in osteoarthritis. A Q angle greater than 15 degrees in females and greater than 8 degrees to 10 degrees in males is considered abnormal.³⁰ Patellar mobility should be assessed using a quadrant system for passive mediolateral displacement of the patella relative to the trochlear groove. The normal patella should not be displaced medially or laterally beyond the second quadrant. Any abnormality in mobility may stem from changes in the tightness of the retinaculum. The apprehension test is performed by attempting to subluxate the patella with the knee in extension. The test is positive when it elicits pain and an unwillingness to allow the examiner to move the patella laterally (Figure 48-17).

At the conclusion of the history and physical examination, the astute clinician should have formulated a short list of possible diagnoses. With this list in mind, the appropriate imaging studies can now be obtained. The goal of the initial imaging studies should be to confirm the diagnosis with the most appropriate and least expensive study. Advanced imaging studies should not replace a thorough history and physical examination.

Imaging

Conventional Radiographs

Conventional roentgenograms are usually the first study obtained after knee injury and should be read in a systematic fashion. Soft tissues should be evaluated before examining the bony structures. Findings should be described in terms of radiolucent and radiopaque lines. Only after the findings

Figure 48-17 The apprehension test is positive when subluxation of the patella causes pain.

have been described should the interpretation phase begin. It is the natural tendency to bypass the description and proceed directly to interpretation. If this is done, it is likely that certain findings will be missed or dismissed prematurely.

The basic radiographic evaluation of the knee consists of standing anteroposterior (AP) weight-bearing, lateral, and Merchant's views. The AP view allows for evaluation of coronal alignment and height of the tibiofemoral joint spaces. The normal coronal alignment of the knee should be 5 to 7 degrees of anatomic (tibiofemoral) valgus. The lateral tibiofemoral joint space should be wider than the medial tibiofemoral joint space in a normal knee. The presence of marginal osteophytes, joint space narrowing, subchondral sclerosis, and cystic change will be seen in the presence of osteoarthritis (Figure 48-18). Periarticular

Figure 48-18 Standing anteroposterior (A), lateral (B), and Merchant's (C) views of an osteoarthritic knee.

Figure 48-19 Standing AP (A), lateral (B), and Merchant's (C) views of the knee in a patient with rheumatoid arthritis.

osteopenia, concentric joint space narrowing, and a paucity of osteophytes are commonly seen in inflammatory arthritis (Figure 48-19). The lateral radiograph allows for evaluation of an effusion, patella tendon length, and the quadriceps tendon. The Merchant's view is taken tangential to the patellofemoral joint.³¹ It allows for detection of patellofemoral arthritis and malalignment.

Additional views include a posteroanterior (PA) standing view with the knees flexed approximately 45 degrees, the tunnel or intercondylar notch view, and the 36-inch AP standing view of bilateral lower extremities. The flexed PA standing view is taken with the radiographic beam directed 10 degrees caudad from anterior to posterior. This allows for evaluation of the posterior femoral condyles for joint space narrowing.³² The tunnel view is obtained with the knee flexed and the radiographic beam directed inferiorly at an angle perpendicular to the tibial plateau. It is useful in detecting posterior tibiofemoral joint space narrowing, tibial spine fractures, loose bodies, and osteochondral lesions on the medial aspect of the femoral condyles. The 36-inch standing view is used for determining the mechanical axis of the lower extremity and evaluating any deformity that may be present. The normal mechanical axis is a straight line joining the center of the hip, knee, and ankle joints. Surgeons use it for preoperative planning and postoperative evaluation in total knee arthroplasty, as well for the planning of distal femoral and proximal tibia osteotomies in arthritis surgery.

Computed Tomography

Computed tomography (CT) has largely been replaced by magnetic resonance imaging (MRI) in evaluation of routine knee problems. CT is now used primarily for detection of bony tumors and in the trauma setting for detection of subtle fractures that are not easily visualized with conventional radiographs, as well as for a more thorough evaluation of intra-articular fractures. In cases of distal femoral or proximal tibia fractures, CT is used to help the surgeon plan operative treatment. CT is also used to assess axial alignment of the femoral and tibial components in cases of the painful total knee arthroplasty.^{33,34}

Ultrasound

The use of ultrasound has become more common in the diagnosis of knee disorders due to recent improvements in transducer technology. Ultrasound is an attractive imaging modality because of its low cost, real-time capabilities, and portability. The ability to perform provocative maneuvers during sonography is particularly appealing. Ultrasound can easily and reliably detect joint effusions, as well as quadriceps and patella tendon disruptions. It has been reported that ultrasound can detect a 1-mm increase in joint fluid.³⁵

Nuclear Scintigraphy

Nuclear scintigraphy is sensitive but not specific, and it is used to detect areas of increased osseous remodeling. It requires clinical correlation and should be used in conjunction with other imaging modalities. Technetium phosphate compounds are injected intravenously. Approximately 50% of the tracer is excreted by the kidneys, and the remainder is taken up in areas of increased osseous turnover. Imaging of the skeleton is typically performed 2 to 3 hours after injection because this allows for maximum contrast between the soft tissues and the skeletal structures while still providing for an adequate photon count.³⁶

Three-phase bone scanning can yield additional information. The three phases include an angiographic pool, followed by blood pool and bone imaging. The angiographic phases allow for detection of regional hyperemia. This technique has been reported to have greater specificity and can be used in cases of suspected osteomyelitis, osteonecrosis, stress fracture, and implant loosening.³⁶ It has been reported that increased radionuclide uptake can be seen for up to 12 to 18 months after total knee arthroplasty. Asymmetric uptake in one area around the prosthesis should raise the question of loosening or periprosthetic fracture (Figure 48-20).^{37,38} Addition of labeled leukocytes to the technetium 99m sulfur colloid yields an 80% sensitivity and 100% specificity for diagnosing infection.³⁹

Magnetic Resonance Imaging

MRI has supplanted many imaging modalities due to its direct multiplanar capabilities and superior soft tissue contrast. Although conventional radiographs remain the gold standard for defining osseous structures, MRI provides excellent visualization of articular cartilage, the cruciate ligaments, the collateral ligaments, the patella tendon, the

Figure 48-20 A bone scan reveals increased uptake of radiotracer around the distal femur in this patient with an infected total knee arthroplasty and septic loosening of his femoral component.

quadriceps tendon, and the menisci (Figure 48-21). It is also highly sensitive for detecting bone marrow edema (contusion), stress fractures, and mass lesions. Use of the “two-slice touch” rule has improved the sensitivity and specificity of MRI in accurately diagnosing meniscal tears. This rule classifies a meniscus as torn if there are two or more magnetic resonance (MR) images with abnormal findings and as possibly torn if there is only one MR image with an abnormal finding. Using fast spin-echo imaging, the sensitivity and specificity for diagnosing medial and lateral meniscal tears was 95% and 85%, and 77% and 89%, respectively. This translates to a positive predictive value of 91% to 94% for medial meniscus tears and 83% to 96% for lateral meniscus tears.⁴⁰

Figure 48-21 This sagittal magnetic resonance image shows linear signal change extending to the meniscal surface consistent with a tear in the posterior horn of the medial meniscus.

Common Disorders in the Differential Diagnosis of Knee Pain

General

Though many diseases may involve the knee, a limited number are encountered frequently. In evaluating the complaint of knee pain, the clinician should be familiar with osteoarthritis; rheumatoid arthritis; inflammatory arthritis associated with the seronegative spondyloarthropathies; tears of the menisci, ligaments, and tendons; osteochondritis dissecans; osteochondral fractures; fractures; referred pain from the hip (such as with slipped capital femoral epiphysis in adolescents); vascular claudication; neurogenic claudication; complex regional pain syndrome; sarcoma; metastases; and infection.

Bursitis

The prepatellar bursa lies between the retinaculum and the subcutaneous fat and runs from the patella to the tibial tubercle. The bursa may become inflamed and fill with fluid when exposed to a direct blow or repetitive microtrauma (kneeling). Patients with prepatellar bursitis present with anterior knee pain on flexion and a fluctuant mass over the anterior knee. If the area becomes warm, tender to palpation, and erythematous, septic bursitis should be ruled out with aspiration. The pes anserinus bursa, located over the insertions of the sartorius, gracilis, and semitendinosus muscles on the proximal medial tibia, can also be a source of knee pain if inflamed.

Neoplasia

Tumors around the knee are often diagnosed after trauma prompts medical evaluation. Pain at night, pain at rest, and constitutional symptoms should alert the clinician

to consider the appropriate workup. Some of the benign tumors seen around the knee include enchondroma, pigmented villonodular synovitis, osteochondromatosis, and giant cell tumor. Malignant tumors seen around the knee include, but are not limited to, metastases, osteosarcoma, Ewing's sarcoma, chondrosarcoma, and malignant fibrous histiocytoma.

Popliteal Cysts

A popliteal cyst, originally called Baker's cyst, is a synovial fluid-filled mass located in the popliteal fossa. The most common synovial popliteal cyst is considered to be a distention of the bursa located beneath the medial head of the gastrocnemius muscle. Usually, in an adult patient, an underlying intra-articular disorder (osteoarthritis) is present. In children, the cyst can be isolated and the knee joint normal. Patients usually present with episodic posterior knee pain.⁴¹ The diagnosis is made by ultrasonography or MRI. Treatment options include benign neglect, aspiration, surgical excision, or removal of the underlying pathology (arthritis) with knee arthroplasty.

HIP PAIN

History

Taking an accurate history is an important initial step in formulating a differential diagnosis for patients who present with a complaint of hip pain. In general, more conditions should be considered in the differential diagnosis for hip pain than for knee pain because the hip is a common site for referred pain from lumbosacral and intrapelvic pathology. A detailed, comprehensive history will direct the clinician to a focused physical examination.

Most patients who present with hip pathology will complain of pain. It is important to define the exact location of the pain because "hip" pain may refer to discomfort in the groin, lateral thigh, or buttock. Pain in the groin or medial thigh region is most often due to hip disease and is believed to arise from irritation of the capsule and/or synovial lining.⁴² Pain generated in the lumbosacral spine may be referred to the buttocks and/or lateral thigh.⁴³ Lateral thigh pain may stem from so-called trochanteric bursitis (usually abductor tendinitis) as well. Activities or positions that aggravate and relieve the pain should be explored. The severity, frequency, and patterns of radiation of the pain should also be evaluated. It is not uncommon for knee pain to be generated from the hip joint. Metastatic and primary tumors that occur in the pelvic and proximal thigh regions should always be included in the differential diagnosis. Intrapelvic pathology from the prostate, seminal vesicles, hernias, ovaries, gastrointestinal (GI) system, and vasculature should also be considered.^{44,45}

Knowledge of the patient's general level of functioning is important because this will lend insight into the severity of disease and may influence treatment. Patients with hip pathology may have difficulty trimming their toenails, donning shoes and socks, and using stairs. Walking tolerance and use of assist devices should also be recorded. The Harris Hip Score and WOMAC Osteoarthritis Index are two rating scales that are widely used to assess function in this patient population.^{46,47}

The patient should be asked about any hip problems that he or she encountered in childhood. Diseases such as developmental dysplasia, slipped capital femoral epiphysis, Legg-Calvé-Perthes disease, polio, and trauma may lead to osteoarthritis later in life.⁴⁸⁻⁵⁰ Any treatment rendered for these diseases should be asked about as well.

Osteoarthritis and inflammatory arthritis are two common causes of hip pain. In general, pain from osteoarthritis will be exacerbated by activity and relieved by rest. Mild arthritis of the hip may not become symptomatic until a certain activity level is reached. Stiffness (usually from synovitis) is also a common complaint with both degenerative and inflammatory arthritis. When the hip pain continues despite a trial of rest, an underlying inflammatory or infectious process should be considered. The American Rheumatism Association revised their classification of rheumatoid arthritis in 1988. The current criteria include 1 hour of morning stiffness for 6 weeks, symmetric joint swelling in at least three joints, subcutaneous nodules, typical radiographic changes, and a positive rheumatoid factor.⁵¹

Any previous treatments for hip pain should be discussed. The patient's response to nonsteroidal anti-inflammatory medications, nutritional supplements (e.g., chondroitin and glucosamine), physical therapy, corticosteroid injections, local anesthetic injections, hyaluronic acid injections, ultrasound, and operative interventions should be recorded. Lastly, a more general medical history should be explored. The physician should be aware of alcoholism, neuromuscular disorders, smoking history, and general support systems.

Physical Examination

The physical examination of the patient with hip pain begins as the clinician watches the patient for the first time. Ease of chair rise, postures, and walking speed all provide insight into the extent of a patient's disability. A general evaluation of the patient's spine, lower extremity alignment, and leg lengths comes next. With the examiner behind the patient, the spine is examined for coronal and sagittal balance. The patient is asked to touch his or her toes. A rib hump indicates the presence of scoliosis. Any gross deformity of the spine will alert the examiner to the potential of a pelvic obliquity and resultant leg-length discrepancy. The overall coronal alignment of the lower extremities is evaluated next. If a leg-length discrepancy is detected, blocks can be used, as discussed previously, to determine the amount of apparent inequality. If the leg-length discrepancy is due to a fixed pelvic obliquity from lumbosacral disease, blocks may not be able to level the pelvis. Previous surgical scars about the hip are noted. Palpation of the bony landmarks (iliac crest, anterior superior iliac spine, posterior superior iliac spine, ischial tuberosity, coccyx, spinous processes, and greater trochanter) should be performed (Figure 48-22). The femoral neck is located approximately three fingerbreadths below the anterior superior iliac spine.

A basic evaluation of gait should be performed. Though gait analysis is a complex science, all clinicians should feel comfortable evaluating for common abnormalities. The patient with hip pain may present with an antalgic gait. The severity of the limp should be classified as mild, moderate, or severe. Mild limps can only be detected by trained

Figure 48-22 Diagram of the bony landmarks on the pelvis that can be palpated during physical examination.

observers. Moderate limps will be noticed by the patient. A severe limp will be readily apparent and have a significant impact on speed of ambulation. Common causes of limp include pain and abductor (gluteus medius and gluteus minimus) weakness. Differentiating between these two etiologies of limp is an important part of the physical examination.

The patient with abductor dysfunction will likely have an abductor, or Trendelenburg lurch.⁵² With a Trendelenburg lurch, the patient compensates for abductor dysfunction by leaning over the involved hip to shift the body's center of gravity in that direction (Figure 48-23). If the patient has a Trendelenburg lurch, we proceed to evaluate for a Trendelenburg sign. A positive Trendelenburg sign

Figure 48-23 Physical examination of abductor function: **A**, Normal single-legged stance. **B**, Positive Trendelenburg lurch and negative Trendelenburg sign. **C**, Positive Trendelenburg lurch with pelvic obliquity and leaning over the involved hip to shift the body's center of gravity.

occurs when the pelvis tilts toward the unsupported side during one-legged stance. This test is best performed with the examiner behind the patient. Causes of abductor weakness are numerous and may include a contracted or shortened gluteus medius, coxa vara, fracture, dysplasia, neurologic conditions (e.g., superior gluteal nerve injury, radiculopathy, poliomyelitis, myelomeningocele, spinal cord lesions), and slipped capital femoral epiphysis.

The patient is then asked to lay supine on the examination table. The range of motion of both hips should be evaluated by recording flexion, extension, adduction, abduction, internal rotation in extension, and external rotation in extension. Hip extension is best evaluated with the patient in the prone position. Normal range of motion values include 100 to 135 degrees for flexion (knee should be flexed to relax the hamstrings), 15 to 30 degrees for extension, 0 to 30 degrees for adduction, 0 to 40 degrees for abduction, 0 to 40 degrees for internal rotation, and 0 to 60 degrees for external rotation. Motion is often limited in cases of deformity (such as limited internal rotation in slipped capital femoral epiphysis) and advanced osteoarthritis. Internal rotation and abduction are usually the first motions to be limited in osteoarthritis. Motion will be painful in patients with synovitis as well. Areas that are painful should be palpated.

A series of special tests can be performed to evaluate for subtle muscle contractures and limitation of motion. The presence of a hip flexion contracture is common in patients with moderate to severe hip pathology and can be quantified with the Thomas test (Figure 48-24).⁵³ This test is performed by having the patient bring his or her thighs to their chest while in the supine position. This allows for flattening of the spine, and the hip to be evaluated is allowed to extend to neutral. If the patient is unable to reach neutral, the amount of flexion contracture is recorded. The Ober test measures tightness of the iliotibial band. The patient lies on the unaffected side and the examiner helps the patient abduct the hip with the hip extended and the knee

Figure 48-24 In the Thomas test, a hip flexion contracture is measured by flexing the contralateral hip to eliminate compensatory lumbar lordosis. The ipsilateral hip is then allowed to extend with gravity. The angle between the examination table and the thigh is the degree of flexion contracture.

flexed to 90 degrees. The leg is slowly released from abduction to neutral, and the hip will remain abducted if there is contracture of the iliotibial band. Ely's test will detect a tight rectus femoris. The knee is passively flexed with the patient in the prone position. If the rectus femoris is tight, the ipsilateral hip will spontaneously flex. If the rectus femoris is normal, the hip will remain flush with the examination table.

Patients will occasionally complain of a “snapping” sensation in their hip. Although it may be difficult for the clinician to reproduce snapping, patients may be able to demonstrate this by flexing and internally rotating their hip. Extra-articular causes of hip snapping include a thickened iliotibial band snapping over the greater trochanter, the iliopectas tendon gliding over the iliopectineal eminence, the long head of the biceps tendon rubbing on the ischial tuberosity, and the iliofemoral ligament rubbing on the femoral head. Intra-articular causes of snapping hip syndrome include loose bodies and large labral tears.

In addition to using blocks with the patient standing, leg lengths can be measured while the patient is in the supine position (Figure 48-25). The *apparent* leg length is the distance from the umbilicus to the medial malleolus. The *true* leg length is measured from the anterior superior iliac spine to the medial malleolus. Pelvic obliquity and abduction/adduction of the hip will create an apparent leg-length discrepancy.

Sacroiliac disease should be included in the differential diagnosis of hip pain. Although multiple provocative tests have been described to elicit sacroiliac disease, the flexion in abduction and external rotation (FABER) test (also known as Patrick's test) can help distinguish between hip and sacroiliac joint pathology. With the patient supine, the clinician has the patient place his or her hip in the flexion, abduction, and externally rotated position. The clinician then presses the flexed knee and the contralateral anterior superior iliac spine toward the floor. Pain in the buttocks suggests sacroiliac joint disease, whereas pain in the groin

points to hip pathology. If the sacroiliac joint is implicated, it is recommended that multiple other provocative tests be performed. It has been shown that by using a combination of the distraction, thigh thrust, compression, sacral thrust, Gaenslen's, and FABER tests, sacroiliac joint pathology is the likely pain generator when three or more of the tests are positive.^{54,55}

The acetabular labrum is drawing attention as a previously underappreciated cause of hip pain. Clinical presentation of a labral tear of the acetabulum may be variable, and the diagnosis is often delayed. Patients usually see multiple providers before the diagnosis is confirmed. In a series of 66 patients with arthroscopically confirmed tears of the acetabular labrum, 92% of the patients complained of groin pain, 91% of the patients had activity-related pain, 71% of the patients complained of night pain, 86% of the patients described the pain as moderate to severe, and 95% of the patients had a positive impingement sign. The authors recommended that a diagnosis of acetabular labral tear be suspected in young, active patients complaining of groin pain with or without trauma.⁵⁶ The positive impingement test helps confirm the diagnosis of labral tear. The test is positive if the patient experiences groin pain with the hip flexed, adducted, and internally rotated. The positive predictive value of this test has been shown to range from 0.91 to 1.00 in six different studies.⁵⁷⁻⁶²

A thorough evaluation of the neurovascular system should be completed after the musculoskeletal portion of the physical examination for the hip or knee is completed. This should include palpation or Doppler evaluation of the femoral, popliteal, dorsalis pedis, and posterior tibial arteries, as indicated. Strength testing with resisted isometric movements for each muscle in the lower extremity is performed, with 5 being normal strength, 4 being full motion against gravity and against some resistance, 3 being fair motion against gravity, 2 being movement only with gravity eliminated, 1 being evidence of muscle contraction but no joint motion, and 0 being no evidence of contractility.

Figure 48-25 Measurement of leg lengths: **A**, The apparent leg length is the distance from the umbilicus to the medial malleolus. **B**, Pelvic obliquity causing an apparent leg-length discrepancy. **C**, The true leg length is the distance from the anterior superior iliac spine to the medial malleolus.

Figure 48-26 An anteroposterior pelvis demonstrates the characteristic joint space narrowing, cystic changes, and osteophytes seen in osteoarthritis.

Sensation in the lower extremity should be evaluated by assessing for light touch and/or appreciation of pin prick in a dermatomal distribution. Patellar and ankle reflexes should be tested. Lastly, the examiner should test for any abnormal clonus and Babinski reflexes as indicated.

Imaging

Conventional Radiographs

Plain radiographs remain the primary diagnostic imaging tool for the evaluation of hip pathology. All other imaging modalities should be viewed as complementary to conventional radiographs. Our standard screening series includes a low anteroposterior (AP) pelvis ([Figure 48-26](#)), an AP hip ([Figure 48-27](#)), a frog-lateral view, and a cross-table lateral view. The frog-lateral view provides a lateral of the proximal femur and is useful for detecting femoral head collapse (as seen in osteonecrosis, [Figure 48-28](#)). Numerous other special radiographs of the hip exist including Judet 45-degree oblique views and the false profile view. Judet views allow for easier visualization of the anterior (obturator oblique) and posterior (iliac oblique) columns. The false profile view allows for evaluation of anterior bony coverage of the femoral head in cases of acetabular dysplasia. Developmental dysplasia of the hip (DDH) is common, and we do not recommend the routine use of any special views before referral to an orthopedic surgeon ([Figure 48-29](#)).

Computed Tomography

Computed tomography (CT) is used for assessment of acetabular fractures, acetabular nonunions, femoral head fractures, subtle femoral neck fractures, neoplasia, and bone stock in the revision total hip arthroplasty setting. Due to its limited soft tissue contrast, CT has largely been replaced by MRI for detailed evaluation of the soft tissues around the hip.

Figure 48-27 An anteroposterior hip demonstrating the characteristic concentric joint space narrowing, paucity of osteophytes, and periarticular osteopenia seen in rheumatoid arthritis.

Nuclear Scintigraphy

The role of bone scanning in the evaluation of hip pathology is similar to its role in the assessment of knee pain. It should always be used in conjunction with other imaging modalities due to its limited specificity ([Figure 48-30](#)).

Magnetic Resonance Imaging

MRI provides unprecedented detail of the soft tissues around the hip joint. Its use is now common for diagnosis of osteonecrosis, labral pathology, neoplasia, effusion, synovitis, loose bodies, tendinitis, transient osteoporosis of the hip,

Figure 48-28 A frog-lateral radiograph demonstrating femoral head collapse from osteonecrosis.

Figure 48-29 An anteroposterior hip radiograph demonstrates osteoarthrosis from developmental dysplasia. The up-sloping lateral edge of the acetabulum is characteristic for developmental dysplasia of the hip.

Figure 48-31 This short tau inversion recovery coronal magnetic resonance image shows a complete avulsion of the gluteus medius tendon from its insertion on the greater trochanter. Note the signal change along the lateral aspect of the greater trochanter, consistent with accumulation of intra-articular gadolinium at the site where the gluteus medius tendon should be.

occult femoral neck fractures, bone edema, gluteus medius tendon avulsions, and nerve injury. MR arthrography of the hip joint is useful for identifying gluteus medius tendon avulsion after total hip arthroplasty (Figure 48-31) and for detecting labral tears. One study showed a 92% sensitivity for the detection of labral tears using MR arthrography.⁶³ Delayed gadolinium-enhanced MRI of cartilage, a

technique designed to measure early arthritis in the hip joint, is now being used clinically in the management of hip dysplasia.⁶⁴ Despite the tremendous diagnostic capabilities of MRI, its ability to detect bony pathology is limited. As such, conventional radiographs remain the imaging modality of choice for the screening of hip pathology.

Figure 48-30 This bone scan shows increased radiotracer uptake at the proximal femur. The patient presented with activity-related thigh pain 1 year after primary cementless total hip arthroplasty. History, physical examination, and conventional radiographs suggested failure of osseointegration. At the time of surgery the femoral component was found to be grossly loose.

Hip Arthrography

Hip arthrography is useful for detecting avulsions of the gluteus medius tendon from the greater trochanter and for differentiating intra-articular hip pathology from lumbosacral disease. In one study, intra-articular anesthetic injection was 90% accurate in predicting intra-articular pathology as confirmed by hip arthroscopy.⁶⁵ Anesthetic arthrogram of the hip has shown a 95% positive predictive value and a 67% negative predictive value for pain relief after total hip arthroplasty in patients with concurrent hip and lumbar osteoarthritis.⁶⁶

Common Disorders in the Differential Diagnosis of Hip Pain

Numerous common causes of hip pain exist, and a detailed discussion of these is beyond the scope of this chapter. The differential diagnosis of hip pain should include osteoarthritis (most frequently from developmental dysplasia, Legg-Calvé-Perthes disease, or slipped capital femoral epiphysis); inflammatory arthritis; osteonecrosis; fractures (acetabulum, femoral head, femoral neck, intertrochanteric, or subtrochanteric); trochanteric bursitis; femoroacetabular impingement; tears of the acetabular labrum; transient osteoporosis of the proximal femur; infection; snapping hip syndrome; osteitis pubis; neoplasia (osteosarcoma, chondrosarcoma, pigmented villonodular synovitis, osteochondromatosis, malignant fibrous histiocytoma, or metastases); inguinal hernia; or referred pain (lumbosacral spine, sacroiliac joint, prostate, seminal vesicles, uterus, ovaries, lower GI tract). This list can be efficiently narrowed down by taking a detailed history, performing a comprehensive examination of the musculoskeletal and neurovascular systems, and obtaining the appropriate imaging studies.

KEY POINTS

The differential diagnosis for foot and ankle pain is vast. Localizing symptoms by anatomic region helps narrow this differential.

On physical examination, most structures in the foot and ankle are immediately subcutaneous and readily palpable.

Beyond medications, useful nonoperative treatments include bracing, footwear modification, orthoses, and physical therapy.

Most surgical procedures in foot and ankle surgery fall into one of the following categories: arthrodesis, arthroplasty, corrective osteotomy, ostectomy, tendon débridement and transfer, and synovectomy. Patient compliance and soft tissue integrity are important factors when considering surgery.

Advances in medical management now make joint-sparing procedures possible in many patients with inflammatory arthritis who previously would have required arthrodesis.

Foot and ankle pain are independent risk factors for locomotor instability, impaired balance, and increased risk for falling, as well as compromised functional activities of daily living.¹⁻⁵ Foot and ankle pain appear to affect approximately one in five middle-aged to older individuals. Interference with daily activities occurs in one-half to one-third of affected individuals but is rarely disabling outside the context of rheumatoid arthritis. Foot and ankle pain is significantly more common in women, a finding that has been attributed to gender-specific footwear.

CAUSES OF FOOT AND ANKLE PAIN

The differential diagnosis of foot and ankle pain is vast and includes conditions of tendons, ligaments, muscle, bone, joints, periarticular structures, nerves, and vessels, as well as referred pain (Table 49-1).

The most common cause of pain of the foot and ankle is osteoarthritis (OA). Although OA is the most prevalent joint disease, its pathophysiology remains poorly understood. Research regarding foot and ankle OA in particular is limited by absence of a standard case definition. Ankle and foot OA results from damage and loss of the articular cartilage, which can cause inflammation, stiffness, pain, swelling, deformity, and limitation of function, such as walking or standing. Osteophyte formation can lead to impingement and further pain. In the foot, OA most commonly occurs in the big toe, the midfoot, and ankle. In the early stages, pain may occur only at the beginning and at

Foot and Ankle Pain

MARK D. PRICE • CHRISTOPHER P. CHIDO

the end of an activity, but as the condition progresses it can become constant, even at rest.

The ankle is a complex joint that is subjected to enormous forces during daily activities and in sports, especially running. It is also the joint most commonly injured in the human body. This combination of factors predisposes the ankle joint to degenerative changes, although the risk is lower than other weight-bearing joints, such as the hip and knee. The ankle also rarely develops arthritic changes without an identifiable cause. The most common cause of ankle OA is trauma and can develop following a fracture or repeated sprains. Other causes of OA are abnormal foot mechanics (flat and high-arched feet) and, rarely, systemic diseases such as hemochromatosis.

Foot and ankle pain is the presenting complaint in approximately 15% to 20% of newly diagnosed rheumatoid arthritis (RA) patients.⁶ Further, of those patients already diagnosed with RA, the prevalence of foot and ankle involvement has been estimated to be greater than 90%.⁷

Evaluation of the rheumatoid foot and ankle begins with a thorough history and physical examination. The location, timing, and duration of symptoms can help establish a specific diagnosis and help guide the subsequent course of treatment. Radiographs and advanced imaging modalities provide useful adjuncts in the evaluation of specific foot and ankle pathologies.

The treatment of the rheumatoid foot and ankle is aimed at both alleviating pain and preserving function (i.e., maintaining the ambulatory status of the patient). Initial nonoperative treatment includes medical management, physical therapy, footwear modification, orthotics, and bracing. These measures provide substantial relief for many. For recalcitrant symptoms, surgical intervention may be necessary. Most surgical procedures fall into one of the following general categories: arthrodesis (joint fusion), arthroplasty (joint replacement), corrective osteotomy, ostectomy, and synovectomy (joint or tendon).

FUNCTIONAL ANATOMY AND BIOMECHANICS

The ankle, or tibiotalar joint, is composed of the articulation between the foot (talus) and the lower leg (distal tibia and fibula). Its primary motion is plantar flexion and dorsiflexion in the sagittal plane. In addition, the articulation between the distal tibia and fibula allows a lesser amount of internal and external rotation to occur in the axial, or transverse, plane.

The foot may be loosely divided into three anatomic regions: forefoot, midfoot, and hindfoot. The forefoot

Table 49-1 Differential Diagnosis of Foot and Ankle Pain

Tendon, Ligament, and Muscle
Gastroc-soleus strain
Plantaris rupture
Anterior talofibular ligament tear
Calcaneofibular ligament tear
Deltoid ligament tear
Anterolateral impingement due to complete tear of anterior talofibular ligament and anterior inferior tibiofibular ligament
Syndesmotric impingement due to tear of syndesmosis
Sinus tarsi syndrome (lateral hindfoot pain and instability due to injury of contents of the sinus and tarsal tunnel)
Achilles tendinitis
Achilles rupture
Plantar fasciitis
Posterior tibial tendon dysfunction
Flexor hallucis longus dysfunction
Tibialis anterior tendon tear
Peroneus brevis tendon tear
Bone
Fracture of talus
Calcaneal fracture
Navicular fractures
Lisfranc fracture-dislocation (fracture of the first metatarsal base with dislocation of medial cuneiform)
Metatarsal stress fracture
Freiberg's infraction (sclerosis and flattening of the second metatarsal head due to trauma or microtrauma)
Avascular necrosis of the talus
Fracture of the phalanges
Fracture of the sesamoids
Sesamoiditis
Metatarsalgia
Joint
Osteoarthritis
Gout
Rheumatoid arthritis
Other inflammatory arthritides
Charcot's joint
Osteochondral lesion of the talus
Periarticular Structures
Shin splint (periosteal avulsion and periostitis at the insertion of the medial soleus due to repetitive overuse, such as in running and hiking)
Hallux rigidus
Hallux valgus
Ingrown toenail
Toe deformities
Turf toe (sprain of the first metatarsophalangeal joint due to hyperextension forces)
Plantar fasciitis
Plantar fibromatosis
Nerves
Anterior tarsal tunnel syndrome (involvement of deep peroneal nerve under the superficial fascia of the ankle)
Morton's neuroma
Vessels
Atherosclerosis
Compartment syndrome
Referred Pain
Complex regional pain syndrome

consists of the toes and metatarsal bones, along with the metatarsophalangeal (MTP) and interphalangeal (IP) joints. The tarsometatarsal (TMT) joints connect the forefoot to the midfoot, which comprises the three cuneiform bones, the navicular, and the cuboid. Finally, the hindfoot, located below the ankle, consists of the talus and calcaneus. The joints of the hindfoot include the talocalcaneal (subtalar), talonavicular, and calcaneocuboid articulations.

Forefoot and midfoot motion is primarily plantarflexion and dorsiflexion in the sagittal plane, with some secondary pronation and supination in the coronal plane and abduction/adduction in the axial plane. Motion in the hindfoot is primarily composed of inversion/eversion in the coronal plane, with secondary internal/external rotation in the axial plane and plantarflexion/dorsiflexion in the sagittal plane.

Knowledge of these anatomic divisions is important because radiographs often demonstrate polyarticular disease in patients with RA. An intimate understanding of the local anatomy greatly aids in the establishment of an accurate diagnosis and formulation of an appropriate treatment plan.

DIAGNOSTIC EVALUATION

Physical Examination

A thorough physical examination of the foot and ankle begins with gait analysis, even if simply observing the patient enter the examination room. Normal human gait is divided into two phases. The stance phase is the weight-bearing portion of the gait cycle and comprises roughly 60% of normal walking. It begins with heel-strike and then extends through foot-flat to toe-off. Meanwhile, the swing phase of gait extends from toe-off to heel-strike and comprises the remaining 40% of the gait cycle.

Patients with an “antalgic” gait pattern will have a shortened stance phase on the side of the affected limb, as they attempt to more quickly transfer their weight to the non-painful limb. In addition to an antalgic gait, foot and ankle pain often results in the avoidance of ground contact with the painful part of the foot. A further problem noted in stance phase is dynamic collapse of the medial longitudinal arch, most apparent at foot-flat and toe-off.

During the swing phase of gait, a “steppage” gait may be noted. This is characterized by excessive hip and knee flexion to allow a patient's foot to clear the ground in the setting of a footdrop. In patients with RA, it may be caused by attritional rupture of the anterior tibialis tendon, which is the main dorsiflexor of the ankle.

Following gait analysis, the foot and ankle are inspected, both with the patient sitting and standing. The location of swelling is usually well correlated with the joint(s) involved (e.g., ankle vs. talocalcaneal joint). Deformity should also be noted. Commonly seen deformities in patients with RA include hallux valgus, or bunion (Figure 49-1); hammertoes; and flatfoot deformity (characterized by hindfoot valgus/forefoot abduction). Callosities develop over regions of increased pressure and are associated with deformity and fat pad atrophy. Rheumatoid nodules can appear anywhere on the foot but are often found in areas of repetitive trauma (i.e., at the site of irritation from a tight shoe counter). Similarly, ulcerations appear in areas of repeated injury such

Figure 49-1 Clinical photograph of hallux valgus deformity.

as those found in tight-fitting shoes. Finally, wear patterns on shoes should also be noted. As Hoppenfeld observed⁸: “A deformed foot can deform any good shoe; in fact, in many cases the shoe is a literal showcase for certain disorders.”

Following inspection, the foot and ankle are thoroughly palpated. The dorsum of the foot and ankle has little overlying musculature. As such, many of the bones and tendons are immediately subcutaneous and a great deal of information can be gained from palpating these structures. It is helpful to palpate the foot and ankle by anatomic location (i.e., forefoot, midfoot, hindfoot, anterior and posterior ankle).

In the forefoot, the first metatarsal head and MTP joint can be palpated at the base of the hallux (great toe), at the medial aspect of the “ball” of the foot. Proceeding laterally, the lesser metatarsal heads and MTP joints can then be sequentially palpated. In patients with RA, such palpation often reveals tenderness, synovitis, and bursal swelling. In the second and third MTP joints, sagittal plane instability often results from attenuation of the plantar joint capsule. This can be appreciated by gently translating the second and third toes dorsally.

In the hindfoot the calcaneus is readily palpable, and its various parts can be palpated individually. A stress fracture should always be considered in patients with RA. Further, tenderness over the posterior aspect of the bone may indicate Achilles tendinitis while pain over the medial tubercle (palpable on the medial plantar surface) may indicate plantar fasciitis. Tenderness over the “sinus tarsi” of the hindfoot (located laterally, just anterior and distal to the tip of the fibula) indicates talocalcaneal joint pathology. Finally, posteromedial tenderness may be secondary to tenosynovitis, posterior tibial tendinosis, and tarsal tunnel syndrome (usually secondary to adjacent tenosynovitis).

In the ankle joint proper, tenderness over the anterior joint line usually correlates with ankle joint pathology

including arthritis, synovitis, impingement, and osteochondral defect (OCD).

A more detailed description of these conditions and their correlation with anatomic location is provided later in the chapter and in [Table 49-2](#).

Following inspection and palpation, range-of-motion analysis is performed. Passive range of motion of the ankle is normally between 10 and 20 degrees of dorsiflexion and 40 and 50 degrees of plantarflexion. Normal hindfoot inversion and eversion are approximately 20 and 10 degrees, respectively. The first MTP joint should have approximately 45 degrees of “plantarflexion” (flexion) and 70 to 90 degrees of “dorsiflexion” (extension). Deviations from these norms should be noted as part of the standard workup.

Imaging

Despite the abundant availability of advanced imaging modalities such as magnetic resonance imaging (MRI) and computed tomography (CT), radiographs remain the imaging mainstay in the evaluation of foot and ankle pain. Weight-bearing images should be obtained whenever possible because joint space narrowing and deformity may not be apparent in non-weight-bearing images. Standard images consist of weight-bearing anteroposterior, lateral, and oblique views of the foot and anteroposterior, mortise, and lateral views of the ankle. Further radiographic findings of RA include periarticular erosions and osteopenia.

MRI provides reliable imaging of soft tissue structures and can be a useful tool in the evaluation of the rheumatoid foot and ankle. Early in the course of RA, MRI allows one to look for signs of the disease such as synovitis, tenosynovitis, periarticular edema, and bursitis.⁹ Later, MRI is useful in assessing disease progression and extent of joint involvement, as well as in distinguishing between tendon rupture and tendinitis/tendinopathy ([Figure 49-2](#)).

CT scan¹⁰ and nuclear scintigraphy¹¹ are also used in the evaluation of foot and ankle pain. For example, either method can be quite helpful in postoperative evaluation in fusion surgery. Ultrasound is gaining utility as a method to evaluate tendon integrity as well. However, the results are largely technique dependent with minimization of artifacts being of utmost concern. In addition, ultrasound is difficult

Table 49-2 Anatomic Characteristics of Pain in the Foot and Ankle

Location	Dysfunction
Forefoot	Hallux valgus, hammertoes Metatarsophalangeal arthritis/synovitis/ instability
Midfoot	Plantar fasciitis, arthritis, synovitis (rare)
Hindfoot	Hindfoot valgus deformity, arthritis Stress fracture
Anterior ankle	Arthritis, synovitis, impingement, osteochondral defect
Posterior ankle	Achilles tendinitis/tendinosis, bursitis Stress fracture
Posterolateral ankle	Peroneal tendinitis, tear, instability
Posteromedial ankle	Posterior tibial tendinitis/dysfunction Flexor hallucis longus/flexor digitorum longus tendinitis Tarsal tunnel syndrome

Figure 49-2 Axial magnetic resonance image of ankle demonstrating posterior tibial tendon degeneration and synovitis (arrow).

to use in preoperative planning because important landmarks are often not included.¹²

Anesthetic arthrograms are an extremely useful adjunct in diagnosing foot and ankle pain in patients with RA. Given the complex and crowded geometry of the foot and the propensity of RA to affect multiple joints and tendons, it is often difficult to determine if the pain is articular and, if so, which joint is symptomatic. With an anesthetic arthrogram, a mixture of steroid, anesthetic, and contrast material is injected under fluoroscopic guidance into a suspect joint. This allows the clinician to more precisely determine whether or not the injected joint is a significant pain generator. Again, this is especially helpful in the foot and ankle, where multiple joints are in close proximity and may be simultaneously diseased.¹³

COMMON CAUSES OF ANKLE PAIN

From a diagnostic standpoint, it is useful for the clinician to conceptualize ankle pain on the basis of anatomic location. This approach applies to patients with virtually any form of ankle or foot pain, and RA will be used to illustrate how to formulate a differential diagnosis and treatment plan as advances in medical management temper disease and “allow” patients to develop other, noninflammatory disorders.

Anterior Ankle Pain

Anterior ankle pain, in patients both with and without RA, is most often the result of intra-articular pathology. Anteriorly, the ankle joint is not shielded by the malleoli and is immediately subcutaneous. Further, the anterior extensor tendons are typically not prone to the development of tendinitis and tendinosis.

In early RA, synovitis can cause anterior joint line pain, swelling, and tenderness. Clinically, this results in

symptoms of “impingement.” Specifically, patients will note pain with ankle dorsiflexion, such as when they walk up stairs or an incline. On physical examination, there may be anterior tenderness and/or pain with terminal passive dorsiflexion. Anterior osteophyte formation may produce even more pronounced impingement symptoms, although such osteophytes are more commonly seen with OA and long-standing ankle instability.

Central Joint Pain

Two other causes of central ankle pain, stress fracture and osteochondral defect, should be considered. Stress fractures are commonly seen in patients with periarticular and generalized osteopenia. An osteochondral defect (OCD) is a focal defect in the articular cartilage and subchondral bone. These lesions are encountered more commonly in patients without inflammatory arthritis. In the setting of RA, their presence may represent an early manifestation of RA or a separate pathologic process.

Posterior Joint Pain

Posterior ankle pain usually originates from the Achilles tendon, its insertion onto the calcaneal tuberosity, and two associated bursae in this region. The Achilles tendon is the largest tendon in the body but lacks a true synovial lining. As such, isolated Achilles tendinitis is uncommon. In most instances, Achilles pain results from degenerative tendinosis, with or without an overlying tendinitis. Although associated spur formation is common, it is important to remember that Achilles spurs are a manifestation of a disease process. As such, surgeries directed at spur excision also frequently entail tendon débridement and reconstruction, as well as tendon transfer.

The Achilles tendon is protected by two distinct bursae. A more superficial bursa is immediately subcutaneous and becomes inflamed primarily with irritation from ill-fitting shoes with a tight counter (“pump bump”). The “retrocalcaneal” bursa is a larger structure that lies deep to the Achilles. Inflammation of this structure often accompanies Achilles tendinitis/tendinosis. It may also be irritated by an enlarged posterior superior calcaneal tuberosity, sometimes referred to as “Haglund’s” deformity.

Medial and Lateral Ankle Pain

As with anterior, central, and posterior ankle pain, the origin of medial or lateral ankle pain is also anatomically based.

On the medial side, pain directly over the medial malleolus should alert the clinician to the possibility of a stress fracture. Pain anterior to the medial malleolus is usually articular in nature. Pain posterior to the medial malleolus is often caused by inflammation and/or degeneration of the posteromedial flexor tendons. These include the posterior tibial tendon and the flexor hallucis longus and flexor digitorum longus tendons. The posterior tibial tendon is the largest and strongest of the posteromedial flexor tendons. Its primary function is to invert the hindfoot and thus support the medial longitudinal arch of the foot. Long-standing synovitis and dysfunction of this tendon may ultimately lead

to collapse of the arch and the development of an acquired flatfoot deformity.

On the lateral side of the ankle, pain directly over the lateral malleolus may be caused by a stress fracture. This is especially relevant in the setting of hindfoot valgus and a flatfoot, which will increase fibular loading. Similar to the medial side, pain anterior to the lateral malleolus is usually articular in nature. Finally, pain posterior to this lateral malleolus is usually indicative of peroneal tendon pathology. In patients with RA, the peroneal tendons may be affected by tenosynovitis, longitudinal “split” tears, and chronic tendon instability. With the latter, the tendons sublux over the posterolateral edge of the fibula, causing pain as well as attritional tearing.

COMMON CAUSES OF FOOT PAIN

Typically, the forefoot is the most common site of involvement early in the course of diseases such as RA but also can occur in gout and OA.¹⁴ The pathogenesis of forefoot pain and deformity in the rheumatoid forefoot is inflammation and progressive synovitis that eventually leads to a capsular distention at the MTP joints and destruction of the plantar plates.¹⁵ Eventually it progresses to loss of collateral ligament stability and, finally, destruction of the articular cartilage and bone (Figure 49-3A and B). Clinically, this manifests as dorsal subluxation or dislocation of the lesser toe MTP joints with a hallux valgus deformity and presents as metatarsalgia.

In the lesser MTP joints, loss of stability leads to progressive deformity secondary to the various forces on the forefoot. Muscle imbalance and dorsiflexion forces at toe-off lead to progressive subluxation and even dorsal dislocation of the MTP joints. With this, the metatarsal head is prone to forming keratotic skin lesions that can ulcerate. Muscle imbalance can also lead to the development of painful hammer toe and claw toe deformities that can exert a plantar-directed force that further exacerbates symptomatic

metatarsalgia. Lesser MTP joint subluxation has been reported to be as high as 70% with a concomitant incidence of pressure sores in approximately 30% of those patients.

In the hallux, RA can cause both articular erosions and loss of capsular integrity that often results in the development of a hallux valgus deformity, or bunion (see Figure 49-1). The progression of this deformity may be further accelerated by loss of support from the adjacent lesser MTP joints. The incidence of hallux valgus deformity in patients with RA has been estimated to be up to 70%.

The midfoot is a less common site of involvement in the rheumatoid foot. Radiographically there can be erosions; however, the prevalence of symptoms is often quite low. The most frequent site of involvement is the first tarsometatarsal (TMT) joint. The symptoms seen here, though, may not be from rheumatoid synovitis per se, as seen in the forefoot. Rather, pain may also be due to hindfoot and hallux valgus deformities that lead to increased stresses across the TMT joint. Eventually this increased stress can lead to dorsiflexion of the first TMT joint and resultant lesser toe TMT joint abduction and dorsiflexion, thereby leading to pain in the dorsomedial midfoot. In addition, progressive biomechanical changes can lead to OA of the midfoot TMT joints yielding discomfort and pain with weight bearing.

The three joints of the hindfoot (talonavicular, talocalcaneal, and calcaneocuboid) are commonly affected by RA. Although these joints are affected at different rates, the overall prevalence of hindfoot involvement in RA is between 21% and 29%. The talonavicular joint is most often affected, followed by the talocalcaneal and then calcaneocuboid joints. Further, the hindfoot becomes more symptomatic and involved the longer the duration of RA. The incidence of hindfoot deformity in those with RA less than 5 years has been estimated to be 8% and increases to 25% in those with RA longer than 5 years.¹⁶ Clinically, patients with talocalcaneal or calcaneocuboid involvement will complain of lateral hindfoot pain. Meanwhile, arthritis and synovitis of the talonavicular joint are manifested by dorsal or medial pain.

The deformity most often seen in patients with hindfoot RA is an acquired flatfoot deformity, characterized by heel valgus and forefoot abduction. This usually results from articular deformity and instability but may also be caused by tenosynovitis and tendinosis of the posterior tibial tendon, the main supporter of the longitudinal arch of the foot.

NONOPERATIVE TREATMENT

Medical management remains the cornerstone of treatment for many forms of foot and ankle arthritis. In fact, many of the current recommendations for operative treatment may soon be modified given the alteration of disease progression with current medical regimens for RA.¹⁷ The most common medical management still consists of nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, and disease-modifying antirheumatic drugs (DMARDs) and, more recently, biologic therapies. Although each of these drug classes has done much to alleviate patient suffering, they are not without impact on the surgical management of rheumatic disease. There is concern about lower fusion rates in

Figure 49-3 Preoperative (A) and postoperative (B) anteroposterior radiograph of hallux valgus deformity with lesser metatarsophalangeal joint erosions treated by fusion and lesser metatarsal head resections.

the setting of NSAIDs and increased infection rates in the setting of steroids or DMARDs.^{18,19} Moreover, those who have been on chronic steroids are at risk for postoperative adrenal insufficiency and may require perioperative corticosteroids.²⁰ Close communication and collaboration between the rheumatologist and surgeon are essential to good outcomes.

Footwear modification can often have profound benefits for patients. Shoes should be examined in the clinic to be sure that they can accommodate a patient's deformity. Patients often feel best in shoes with a deep, wide toe-box, a firm heel counter, and soft heel. Well-constructed walking or jogging shoes usually provide sufficient room for mild to moderate deformities. It is helpful to provide patients with a list of suitable manufacturers when making such recommendations.

Often it is necessary to prescribe a custom orthotic insert for those with more moderate deformities. Typically the insole of the shoe must be removed in order to make room for the orthotic. Again, most walking or jogging shoes will suffice. In general, custom orthotics can be divided into rigid, semirigid, and softer accommodative devices. Rigid and semirigid orthotics are usually used to correct supple deformities and should be used with caution in patients with RA.²¹ More commonly, patients benefit from accommodative orthotics (i.e., orthotics made of softer material that can be molded to "accommodate" a deformity).²² These can then be further modified by incorporating a "relief" under a deformity, thereby further unloading it. When sending patients for orthotics, it is best to provide the orthotist with a prescription that includes the patient's precise diagnosis (e.g., RA or OA with metatarsalgia), as well as the type of orthotic and any modifications desired (e.g., a "custom accommodative orthotic with a relief under the lesser metatarsal heads").²³

Finally, injections of a mixture of anesthetic and corticosteroid to areas of inflammation or bursitis are useful in the treatment of both inflammatory and noninflammatory conditions affecting the foot and ankle. In the foot and ankle, however, such injections must be judiciously employed. Most importantly, injections into and around tendons should be avoided. Due to the forces associated with weight bearing and ambulation, these tendons are under substantial load. The injection of a corticosteroid directly into or even near a tendon can adversely affect the biomechanical properties of the tendon, ultimately leading to rupture.²⁴ A further precaution is to avoid corticosteroid injections into the lesser MTP when there is evidence of joint instability (manifested by valgus or varus deviation on radiographs or sagittal plane instability on physical examination). Such injections can lead to further attenuation of the joint capsule and can result in frank joint dislocation.

OPERATIVE TREATMENT

If symptoms persist despite nonoperative management, surgical intervention should be considered. Two important factors must be taken into account when deciding whether or not to proceed with surgery. First, the soft tissues and vascular status must be carefully assessed. Both may be

compromised and could negatively affect outcome. Second, the ability of patients to comply with the postoperative regimen (e.g., being able to use crutches and not bear weight if necessary) must be considered. Even limited non-compliance can lead to a poor outcome, especially in fusion surgery.

As noted earlier, most surgical procedures fall into one of the following categories: arthrodesis (joint fusion), arthroplasty (joint replacement), corrective osteotomy, ostectomy, and synovectomy (joint or tendon).

Arthrodesis

Arthrodesis remains a surgical cornerstone for the rheumatoid foot and ankle. With an arthrodesis procedure, the two sides of the joint are roughened with a burr or small chisel. Next, the two bones to be fused are compressed and fixed together, usually with one or more screws (see [Figure 49-3B](#)). In the weeks and months following surgery, the body is "tricked" into thinking that there is a fracture present at the fusion site and heals this with bone. As such, the two bones become one and are considered fused. Fusion surgery offers reliable pain relief in the majority of patients. One obvious concern with fusion surgery is the loss of motion. For the patient, however, this usually results in only mild functional compromise. Further, to the untrained eye, there is remarkably little change in gait.

Commonly performed fusions in patients with RA include ankle arthrodesis, isolated hindfoot fusions, triple arthrodesis, midfoot arthrodesis, and arthrodesis of the first MTP joint. A triple arthrodesis involves fusion of the talocalcaneal, talonavicular, and calcaneocuboid joints. Together, these joints allow coronal plane motion and thereby are most important when walking on uneven ground.

Fusion remains the gold standard for patients with RA of the ankle. If there is minimal deformity and no loss of bone stock, ankle fusion surgery may be performed arthroscopically or through a "miniopen" approach. These techniques involve less soft tissue dissection and stripping, thereby minimizing loss of bony perfusion. Nevertheless, the time period for which the patient must avoid bearing weight (from 6 to 12 weeks) remains the same. The success rate of ankle fusion surgery in patients with RA is generally 85% or greater. Although the osteopenia associated with the disease can compromise fixation, it can also theoretically enhance fusion because there is less sclerotic subchondral bone.

In the hindfoot, fusion surgery may be performed on one or more of the three joints of this part of the foot (i.e., the talocalcaneal, talonavicular, and calcaneocuboid joints). If only one of these joints is diseased, an isolated fusion of this joint is acceptable.²⁵ This reduces surgical morbidity and the extent of the procedure. Nevertheless, with fusion of just one of the joints of the hindfoot, motion in the other joints is reduced.²⁶ If more than one joint is diseased, a "double" or "triple" arthrodesis is necessary.

In the midfoot, fusion surgery results in negligible loss of motion because the joints of the midfoot normally have less than 10 degrees of motion. With both OA and inflammatory arthritis, symptomatology is most often limited to the medial (first through third) TMT joints. The lateral (fourth

and fifth) TMT joints are infrequently symptomatic, even in the setting of advanced radiographic changes.

Finally, in the forefoot, fusion surgery is indicated only for the first metatarsophalangeal (MTP) joint. This procedure is used for both arthrosis and advanced hallux valgus (bunion) deformities. When the first MTP joint is fused, it is positioned in a slightly dorsiflexed position to assist ambulation. With MTP fusion in 47 feet, Coughlin²⁷ reported 96% good to excellent results and 100% fusion at an average 6.2-year follow-up.

In summary, fusion surgery generally provides reliable pain relief and a stable, plantigrade foot. Nevertheless, the loss of motion of the fused joint can lead to increased motion and altered biomechanics at adjacent joints. This ultimately may lead to arthritic changes in these joints.²⁸ Further, fusion surgery may lead to subtle albeit real changes in gait.²⁹ Finally, the minimal ramifications of fusing just one joint may become much greater in the setting of a subsequent fusion in either the ipsilateral or contralateral limb.

Arthroplasty

Concerns regarding fusion have driven many to work toward improving joint replacement surgery (arthroplasty) in the foot and ankle. Most notably, total ankle replacement surgery continues to evolve and remains a controversial topic among orthopedic surgeons. Although there are many who perform ankle replacement surgery, there are many that do not or that do so only on a limited basis. To this end, the U.S. Food and Drug Administration currently approves only four ankle prostheses for implantation. Long-term survival data as published for hip and knee arthroplasty are not yet available.

The main advantage of ankle arthroplasty is preservation of motion. Its main two disadvantages are technical complexity and the difficulty with subsequent fusion if the procedure fails. In general, ankle replacement surgery is indicated for middle-aged and elderly individuals with low functional demands and minimal deformity. Two other indications especially pertinent in patients with ankle arthritis include (1) bilateral disease and (2) concomitant ipsilateral hindfoot disease or preexisting arthrodesis. The paradox of ankle replacement surgery remains as follows: Ankle replacement is contraindicated in young patients for whom preservation of motion is most important. On the other hand, arthroplasty is more commonly performed in older patients for whom preservation of motion is less important and who would do well with a fusion. Nevertheless, total ankle replacement surgery continues to evolve and reported success rates with modern designs continue to improve^{30,31} (Figure 49-4).

In the foot, arthroplasty is performed by some surgeons for the first MTP joint. The relevant literature is still somewhat conflicted, though. Although there were some encouraging early results with arthroplasty, other studies have shown high rates of implant failure and loosening secondary to synovitis from polymeric silicone (Silastic) particle wear.³²⁻³⁴ Further, advanced deformity, often present in patients with RA, is considered to be a relative contraindication to first MTP joint arthroplasty. Nevertheless, new implant designs may hold increased promise. In general,

Figure 49-4 Anteroposterior radiograph of total ankle arthroplasty.

these implants are lower profile and resect less bone, which also makes it easier to perform a subsequent fusion, if necessary.

Osteotomy

Corrective osteotomies are used primarily for two reasons in the treatment of RA: to correct deformity and/or to redistribute forces on a joint or the terminal aspect of a bone.

Examples of osteotomies to correct deformity include calcaneal osteotomies for pes planovalgus and metatarsal osteotomies for hallux valgus. Previously, patients with RA and concomitant pes planovalgus or hallux valgus underwent fusion surgery. However, with advances in medical management of the disease, it is not unreasonable to attempt joint preservation surgery in patients who have mild to moderate disease, healthy soft tissues, and flexible deformities.

Examples of osteotomies to redistribute forces include tibial osteotomies in the setting of eccentric ankle arthritis and metatarsal osteotomies in the setting of metatarsalgia. Patients requiring surgery for ankle RA previously underwent fusion surgery only, while patients requiring surgery for metatarsalgia underwent metatarsal head resection. Again, however, advances in medical management of the disease allow joint preservation osteotomies to be considered. This is especially the case for metatarsalgia, which is common in patients with RA yet increasingly does not entail frank dislocation or articular erosion.

Ostectomy

Although more commonly seen in patients with OA, some patients with RA may present with symptoms of mechanical ankle impingement arising from anterior bone spurs. In cases without global joint destruction, surgical resection of

the spurs, or cheilectomy, is a reasonable treatment. Although no studies have examined cheilectomy in RA specifically, patients with less severe erosive changes tend to be more satisfied with the results of cheilectomy.³⁵

Synovectomy

For those patients with inflammatory arthritis resistant to medical management and nonoperative treatment, synovectomy can provide a period of pain relief for many patients.^{36,37} It is thought that early synovectomy of either the affected joint or tendon may help halt the progress of joint destruction. Joint synovectomy is indicated in those who have failed medical management yet still have a relatively preserved articular surface. Otherwise, synovectomy of the affected tendons allows some preservation of function.

CONCLUSION

Foot and ankle pain is a prevalent and potentially debilitating problem. Unfortunately, many forms of arthritis, including RA, set up a vicious cycle of foot and ankle pain and biomechanics. Synovitis and articular erosions lead to both pain and deformity. A proper history and physical examination are essential for establishing an anatomic diagnosis. Although advanced imaging modalities such as MRI and CT can be useful as adjuncts, radiography remains the gold standard. Nonoperative modalities such as medications, bracing, physical therapy, orthotics, and footwear modification are able to relieve pain and maintain function for many. For recalcitrant symptoms, substantial relief may be afforded by surgical intervention in the form of arthrodesis, arthroplasty, osteotomy, osteotomy, and synovectomy.

KEY POINTS

Patients with carpal tunnel syndrome typically present with nocturnal paresthesias associated with intermittent pain or paresthesia during the day.

Ganglia are mucin-filled cysts arising from joint capsules or tendon sheaths. If they are particularly symptomatic, corticosteroid injections may be tried, but surgical excision may be necessary to effect a cure.

Tendinitis of the extensor pollicis longus tendon can be particularly dangerous because of the risk of tendon rupture.

De Quervain's disease, inflammation of the extensor pollicis brevis and abductor pollicis longus tendons in the first dorsal extensor compartment, is common in women and is associated with repetitive hand activities such as caring for an infant.

Painful osteoarthritis involving the carpometacarpal joint of the thumb can often be treated successfully by splinting.

Trigger fingers, caused by thickening of the A1 retinacular pulley in the palm, usually can be treated by corticosteroid injections and splinting.

The multiple functions that the hand performs in daily life are usually taken for granted until they become affected by disease or injury. Depending on the nature of the disorder, patients have different capacities to adapt. Patients presenting with pain and dysfunction of the hand or wrist or both represent a wide spectrum, diverse in age, occupations, and avocations. These patients have a broad range of medical conditions that may or may not be related to their current problem. Each patient has a different story to tell about his or her hand and wrist and why he or she is seeking treatment. It is up to the clinician to sort out these various factors, some of which may seem confounding, and determine the most appropriate diagnosis and course of treatment.

This chapter presents guidelines that are useful in the evaluation of patients presenting with hand and wrist pain. Complete coverage of all of the various conditions that can affect the hand and wrist is beyond the scope of this chapter. Instead, the conditions discussed include the most common pathologies seen by general practitioners and hand surgeons. The conditions are grouped by their anatomic area to include pain localized to the volar, dorsal, radial, or ulnar wrist; the base of the thumb; and the palm and digits.

Hand and Wrist Pain

CARRIE R. SWIGART

PATIENT EVALUATION

Anatomy

The complex anatomy of the hand and wrist involves many structures interacting in close proximity to one another. Several different diagnoses can manifest with similar symptom patterns despite varying pathologies. A precise knowledge of the anatomy of the hand and wrist often eliminates several diagnostic considerations on the basis of the physical examination alone. The history of the illness and the examination also help to narrow further investigation by enabling the physician to choose appropriate additional diagnostic tests better. Several common sites of pain in the hand and wrist and their corresponding leading diagnoses are illustrated in [Figure 50-1](#). Pain in one location can have multiple etiologies depending on the patient profile and the history of the problem. A thorough review of the pertinent regional anatomy is important to help differentiate successfully the many possible causes of hand and wrist pain.

History

Important patient factors include age, sex, hand dominance, occupation, and hobbies or sports. When determining the history of the problem, a history of recent or distant trauma should be sought and an estimation of the severity of the trauma should be noted. Next, questions about the duration and frequency of the pain and the intensity and quality should be addressed. The pain of degenerative arthritis is often described as a localized “toothache”-type pain, which is always present at a low level and increases with activity, whereas the pain of tendinitis may be sharp, poorly localized, and present only with activity. Rheumatoid arthritis (RA) manifests initially with hand and wrist involvement in 25% of patients and is characterized by joint effusion, with bilateral hand and wrist involvement and morning stiffness. Nighttime symptoms of a burning-type pain in the hand and wrist that are exacerbated by arm position are often associated with nerve entrapment syndromes. Specific activities that either cause pain or alleviate it should also be noted. Arthritis at the base of the thumb, or first carpometacarpal joint, is often aggravated by opening jars, turning doorknobs, and doing needlework or other hobbies.

PHYSICAL EXAMINATION

A thorough examination of the involved extremity and comparison with the uninvolved extremity are essential. Attention should be paid to abnormalities of the more proximal joints of the elbow and shoulder and the cervical

Figure 50-1 **A**, Palmar and ulnar view of the hand and wrist with areas of pain and tenderness marked with their corresponding leading differential diagnoses. **B**, Dorsal and radial view of the hand and wrist with areas of pain and tenderness marked with their corresponding leading differential diagnoses. ECU, extensor carpi ulnaris; FCR/FCU, flexor carpi radialis/flexor carpi ulnaris; TFCC, triangular fibrocartilage complex.

spine. As the differential diagnosis narrows, the examination should be tailored as needed to include or eliminate any possible systemic etiologies. As with other musculoskeletal examinations, a complete record of the range of motion of the involved joints and comparison measurements of the opposite side should be made. Any difference between active and passive motion should be noted. Careful palpation for the site of maximal tenderness is important in differentiating the source of pain and is particularly important when trying to exclude possible factors of secondary gain. Measurements of grip and pinch strength are also helpful in many situations as a diagnostic aid and a baseline measurement to follow for improvement. Many provocative maneuvers are useful in differentiating etiologies; these are discussed with the specific pathology with which they are associated.

Imaging Studies

Technologic advances have increased the availability of imaging studies for the hand and wrist. Improvements in magnetic resonance imaging (MRI) resolution using small joint coils allow more precise imaging of small structures in

the hand and wrist. Advancements in ultrasound technology have allowed this tool to be increasingly used in the diagnosis of musculoskeletal complaints. With the multitude of ancillary studies available, it is important to be selective in using these to establish or refute diagnostic possibilities. In this era of cost containment, imaging studies should be used most often to confirm a diagnosis rather than to find one. An understanding of the advantages and limitations of each study is necessary to enable using them to their fullest potential.

Plain radiographs are the easiest and most readily available study that can be obtained in most offices. A routine hand or wrist series including anteroposterior, lateral, and oblique views is a useful screening tool but often lacks the specificity required. Depending on the suspected diagnosis, there are many available special views. These are discussed with the specific diagnoses to which they pertain later in this chapter.

If further detail of the bony anatomy is required, computed tomography (CT) is the best available tool today. The most common uses for CT in the hand and wrist include evaluation of intra-articular fractures of the distal radius and metacarpals, scaphoid fractures and nonunions, and intraosseous cysts or tumors.^{1,2}

Advances in ultrasound and MRI technology have enhanced the ability to evaluate the soft tissue structures of the hand and wrist. Smaller ultrasound probes with higher resolution have made it possible to visualize and differentiate structures such as flexor tendons, ganglion cysts, and ligaments. Doppler ultrasound can help to differentiate vascular disorders of the hand. MRI technology is constantly improving and allowing for new uses in the hand and wrist. By altering the parameters of this test, information about anatomy and physiology can be obtained.³ Specific uses of these tests and others such as arthrography and bone scans are addressed with the diagnoses for which they are most useful.

Additional Diagnostic Tests

Neurodiagnostic Tests

Neurodiagnostic tests including nerve conduction studies and electromyography are useful in the diagnosis of suspected neurologic disorders of the upper extremity. Specifying the type and nature of examination required enhances the information gained by these studies. If a nerve compression syndrome such as carpal or cubital tunnel syndrome is suspected, nerve conduction studies may be sufficient without the added cost and patient discomfort of formal electromyography testing. Nerve conduction studies evaluate the speed of conduction of motor and sensory nerves across a set distance at a specific location and compare this with established normal values. A decrease in the speed of nerve conduction, as evidenced by an increase in the latency, is seen with localized nerve compression and is shown in several different nerves concomitantly in demyelinating diseases such as multiple sclerosis. When more severe nerve injuries are suspected or if there is clinical evidence of muscle weakness or atrophy, an electromyogram can be useful to delineate better the extent of the process or rule out a myopathic process.⁴

Injections and Aspirations

The use of injections and aspirations can be therapeutic and diagnostic. A so-called lidocaine challenge can be used to discriminate between different diagnoses when placed precisely in one joint or painful area. Corticosteroids can be given selectively in conjunction with the local anesthetic for more lasting relief and in some cases can be curative.⁵⁻¹¹ Some of the most common sites for injection are the A1 pulley region of the finger for trigger finger, the carpal canal for carpal tunnel syndrome, and the first dorsal compartment of the wrist for de Quervain's disease.

Aspiration of joints or other fluid collections such as ganglia can yield vital diagnostic information and can be therapeutic. If infection is suspected, aspiration should be used to obtain a sample of joint fluid for Gram stain, cell count, and culture. Diagnoses such as gout and pseudogout can be confirmed by crystal analysis under polarized light. Many ganglia and retinacular cysts can be treated temporarily or permanently with simple aspiration.^{12,13}

Arthroscopy

Direct visualization of a joint via arthroscopy can be an invaluable diagnostic tool. Despite the increasing sensitivity of imaging techniques such as MRI, arthroscopy provides a dynamic evaluation that static imaging cannot provide.¹⁴ Since the first published report of a series of cases by Roth and colleagues in 1988,¹⁵ it has become the "gold standard" for evaluation of chronic wrist pain.¹⁶⁻¹⁸ With new surgical techniques being developed, surgeons often can proceed directly to the definitive treatment using arthroscopy entirely or in part.¹⁹⁻²⁴

COMMON ETIOLOGIES FOR HAND AND WRIST PAIN

Wrist Pain: Palmar

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the most commonly diagnosed compression neuropathy in the upper extremity. It usually occurs as an isolated phenomenon, but symptoms of CTS can accompany many systemic diseases such as congestive heart failure, multiple myeloma, and tuberculosis.²⁵⁻²⁸ More commonly, CTS is associated with conditions such as pregnancy, diabetes, obesity, rheumatoid arthritis, and gout.²⁹⁻³⁹

The classic constellation of symptoms consists of nocturnal paresthesias in the affected digits; paresthesias or hypesthesias in the thumb, index, and long fingers; and weakness or clumsiness of the hand. Patients often complain of forearm and elbow pain that is aggravated by activities but is poorly localized and aching in nature. Occasionally, more proximal symptoms such as shoulder pain are the main presenting complaint.⁴⁰ Past reports have indicated a 3:1 prevalence of CTS in women. Approximately half of patients are 40 to 60 years old, although CTS has occasionally been diagnosed in children.^{41,42}

The diagnosis of CTS is usually clinical. Tinel's sign, shown by radiating paresthesias in the median nerve

distribution with gentle percussion over the volar wrist, indicates nerve irritation. Reproduction of symptoms with wrist flexion, as described by Phalen,⁴³ and with the carpal compression test, as described by Durkan,⁴⁴ has been shown to be more specific.⁴⁵ Decreased sensibility and thenar atrophy are late signs seen in advanced median nerve entrapment. Bilateral electrodiagnostic tests, specifically nerve conduction velocity testing, should be used to confirm the diagnosis, particularly in patients claiming a compensable injury or in patients with atypical signs or symptoms. Prolonged motor and sensory latencies across the carpal canal confirm pathologic compression of the median nerve.⁴⁶⁻⁴⁸ In patients with classic clinical findings, a study found that CTS could be diagnosed with a high degree of accuracy on clinical grounds alone and that the addition of electrodiagnostic tests did not increase the accuracy.⁴⁹ When attempting to differentiate CTS from more proximal nerve entrapments such as cervical root compression or thoracic outlet syndrome, the addition of electromyography of the cervical paraspinal muscles and proximal conduction tests (H reflex, f waves) can be useful.⁵⁰

Conservative treatment for CTS consists of splinting of the wrist in neutral position and consideration of oral nonsteroidal anti-inflammatory drugs (NSAIDs) for pain control. Splinting should be used sparingly during the workday to prevent secondary muscle weakness and fatigue but is best prescribed to prevent provocative wrist positioning at night. The splint should not hold the wrist in extension beyond 10 degrees (Figure 50-2). Although splinting may be beneficial for relief of symptoms in cases of mild compression, its long-term effectiveness is limited.⁵¹ The use of vitamin B₆ (100 to 200 mg/day) has been helpful in some cases, but its efficacy has not been confirmed in a randomized trial. The popularity of injections of corticosteroid in the treatment of CTS has waxed and waned over the last half century. Although it has been shown to be quite effective in the short term, the long-term efficacy is mixed.⁵²⁻⁵⁴ Also, injections have been associated with exacerbation of the condition and permanent median nerve injury if performed incorrectly.^{55,56} For these reasons, injections are most often indicated in cases when the condition is thought to be temporary such as with pregnancy or if surgery must be deferred because of a medical condition or major life event.

Figure 50-2 Typical night splint used in the treatment of carpal tunnel syndrome.

Figure 50-3 Usual incision used for release of the carpal tunnel. Note its position just ulnar to the course of the palmaris longus tendon (PL) and the relative position of the flexor carpi radialis tendon (FCR).

Surgical release is indicated for patients with confirmed CTS who have failed a course of conservative treatment. In patients who exhibit late findings of objective sensory loss or thenar atrophy, early surgery should be recommended. The incision for a modern carpal tunnel release is not more than 3 cm long and parallels the skin creases of the palm (Figure 50-3).

Ulnar Nerve Entrapment: Cubital Tunnel Syndrome

Entrapment of the ulnar nerve as it passes through the cubital tunnel just posterior to the medial epicondyle of the elbow can manifest with symptoms localized to the ulnar border of the hand. Medial forearm pain and irritability of the ulnar nerve at the elbow may be associated as well. Presenting symptoms usually consist of paresthesias or numbness or both in the small and ring fingers. Percussion of the nerve in the cubital tunnel elicits Tinel's sign. Prolonged elbow flexion reproduces the symptoms. In contrast to carpal tunnel syndrome, it is not unusual for patients to present with early atrophy of the intrinsic muscles, most easily appreciated in the first dorsal interosseous muscle.

Electrodiagnostic studies can help to confirm the diagnosis and differentiate cubital tunnel syndrome from more distal compression of the ulnar nerve in Guyon's canal (see later). If malalignment of the elbow is present or the patient relates a history of childhood trauma, radiographs should be obtained to rule out a supracondylar or epicondylar malunion. So-called tardy ulnar nerve palsy can develop years after a supracondylar fracture of the elbow.⁵⁷

Conservative treatment includes strategies to help the patient avoid having the elbow flexed for prolonged periods, particularly at night. Soft, or semirigid, elbow splints prevent elbow flexion beyond 50 to 70 degrees. Medial elbow pads can be used if the patient's job or hobbies require resting the medial elbow on a hard surface. NSAIDs can be beneficial in acute or traumatic cases. Surgical decompression of the nerve is indicated if a patient fails to obtain relief from

splinting and activity modification or if there is clinical or electrodiagnostic evidence of muscle denervation.

Ulnar Nerve Entrapment: Guyon's Canal

In 1861 Guyon⁵⁸ published a description of the contents of an anatomic canal at the wrist. The distal branches of the ulnar nerve and the ulnar artery pass through this space. As it exits the canal, the ulnar nerve divides into its sensory and motor branches. Compression of the nerve within or proximal to the canal usually manifests with a combination of sensory and motor symptoms in the ulnar nerve distribution. Patients complain of numbness and paresthesias of the palmar aspect of the ring and small fingers. Motor symptoms are usually described as a cramping weakness with grasping and pinching. As with median neuropathy, atrophy of the intrinsic muscles and objective sensory loss are late findings.

In contrast to carpal tunnel syndrome, in which patients usually have an ill-defined onset of symptoms, ulnar nerve compression in the canal of Guyon is often of more acute onset. It can be associated with repeated blunt trauma,⁵⁹⁻⁶¹ a fracture of the hamate or the metacarpal bases, or occasionally a fracture of the distal radius.^{62,63} Space-occupying lesions such as a ganglion, lipoma, or anomalous muscle can also cause compression.⁶⁴⁻⁶⁸ Because of the difference in etiology, this nerve entrapment syndrome is often not amenable to conservative treatment. If there is an anatomic lesion such as a fracture or a mass, this must be addressed. If repetitive blunt trauma is the cause, without associated fracture or arterial thrombosis, splinting and activity modification can alleviate the symptoms.

Flexor Carpi Radialis and Flexor Carpi Ulnaris Tendinitis

Similar to other tendinopathies around the wrist, irritation of the wrist flexors occurs with stress of the wrist in a particular position. Activities that require forced wrist flexion for prolonged periods or with repetition put patients at risk for inflammation around the flexor carpi radialis tendon⁶⁹ or the flexor carpi ulnaris tendon or both. The condition manifests with tenderness along the course of the tendon, especially near its insertion. Wrist flexion against resistance with radial or ulnar deviation reproduces the symptoms. Treatment consists of splinting and rest, elimination of activities that cause pain, and oral NSAIDs. Injection of corticosteroid into the flexor carpi radialis or flexor carpi ulnaris sheath may be curative. Sharp pain, associated with an intense inflammatory localized reaction, is suggestive of calcific tendinitis and is most commonly seen around the flexor carpi ulnaris tendon.^{70,71} If calcific tendinitis is suspected, a plain radiograph can be useful in confirming the diagnosis but the calcification may not become apparent for 7 to 10 days after the onset of symptoms.

Hamate Fracture

An uncommon and underdiagnosed etiology of palmar pain in young, active individuals is a fracture of the hook of the hamate. These fractures can occur from a fall on an extended wrist, a "dubbed" golf shot, or from forcefully striking a ball with a club or bat. Plain radiographs of the wrist are usually

read as normal. The condition should be established and treated expeditiously because it may lead to ulnar nerve entrapment, ulnar artery thrombosis, or rupture of flexor tendons.⁷² Pain in the base of the palm overlying the hamate is the most common presenting symptom. Often, the pain is present only with the activity that caused the fracture such as driving a golf ball or swinging a bat. Because of the proximity of the ulnar nerve, patients also can have sensory and motor symptoms of distal ulnar neuropathy. Occasionally, in the acute setting, vascular complaints such as cold intolerance or frank ischemia from ulnar artery thrombosis can be the presenting condition.

A carpal tunnel view, obtained with the wrist in a hyperextended position, may show the fracture (Figure 50-4A). Alternatively, a selective CT scan through the hamate is a more accurate way to confirm the diagnosis (Figure 50-4B).⁷³ If diagnosed within 2 to 3 weeks of injury, casting should be attempted to allow the fracture to heal.⁷⁴ If this fails or if the fracture is diagnosed late, surgical treatment is indicated, and most authors favor excision of the hook followed by a gradual return to activities.⁷⁵⁻⁷⁸

Wrist Pain: Dorsal

Ganglion

Ganglia account for 50% to 70% of all soft tissue tumors of the hand and wrist. Of these, 60% to 70% occur around the dorsal wrist. These mucin-filled cysts usually arise from an adjacent joint capsule or tendon sheath. The most

common site of origin is the scapholunate ligament, and the main body of the cyst may be located elsewhere on the dorsum of the wrist and attached to this ligament by a long pedicle. Although most ganglia occur as a well-circumscribed and obvious soft mass, some are subtler and are evident only with the wrist in marked volar flexion. As a result of their characteristic appearance, ganglia are not often misdiagnosed but should be differentiated from the less well-demarcated swelling of extensor tenosynovitis, lipomas, and other hand tumors. Plain radiographs are usually normal but occasionally show an intraosseous cyst or an osteoarthritic joint. Some ganglia may not be clinically apparent and are known as “occult” ganglia. Ultrasound and MRI have been shown to be useful in the diagnosis of these ganglia.^{79,80}

Not all ganglia are painful. Patients may present with complaints of wrist weakness or simply because of the cosmetic appearance of the cyst. In approximately 10% of cases, there is evidence of associated trauma to the wrist. The ganglia may appear suddenly or develop over many months. Intermittent complete resorption followed by reappearance months or years later is common.

Most conservative measures such as splinting and rest have only a temporary effect on ganglia. They tend to diminish in size with rest and enlarge with increased activity. Spontaneous rupture is common, and at one time attempting to rupture the cyst with a heavy object such as a large book was recommended as treatment. Aspiration can be performed but has mixed results because of the thick gelatinous nature of the fluid within the cyst. Even if adequate decompression of the cyst can be achieved, reaccumulation of the fluid usually occurs. Aspiration in conjunction with irrigation or injection of corticosteroids can be effective in alleviating the symptoms for varying periods of time.^{12,13,81}

Occasionally, a ganglion can become so large that it can interfere with the function of the wrist by limiting the motion, especially in extension. Pressure of the mass on the terminal branches of the posterior interosseous nerve may be painful. Excision is generally curative but may result in short-term stiffness and some loss of terminal flexion secondary to surgical scarring. Occasionally, a patient desires excision of the cyst for cosmetic reasons. With proper excision, recurrence is less than 10%,⁸²⁻⁸⁴ but if the dissection is incomplete and fails to identify the origin of the cyst, recurrence rates can be 50%. Arthroscopic resection has been shown to be a safe and effective method of treating dorsal wrist ganglia.^{23,24}

Carpal Boss

Often confused with a dorsal ganglion, the carpal boss is a bony, nonmobile prominence on the dorsum of the wrist. It is an osteoarthritic spur that forms at the second or third carpometacarpal joints.⁸⁵ The boss is most evident with the wrist in volar flexion. Patients usually present with pain and localized tenderness over the prominence. The condition is twice as common in women as in men, and most patients are in their 20s to 30s. It is not unusual for a small ganglion to be associated with the boss. Radiographs are best taken with the hand and wrist in 30 to 40 degrees of supination and 20 to 30 degrees of ulnar deviation to put the bony prominence on profile (the “carpal boss view”).⁸⁶

Figure 50-4 A, Carpal tunnel view radiograph showing a hamate hook fracture (arrow). B, Coronal computed tomography scan showing the same hamate hook fracture.

Conservative treatment consists of rest, immobilization, NSAIDs, and occasionally injection with corticosteroids. If persistently painful despite these measures, surgical excision of the boss may be necessary but is associated with a prolonged recovery and continued symptoms in a high percentage of patients.

Extensor Tendinopathies

The extensor pollicis longus (EPL) tendon can be irritated as it passes around Lister's tubercle. This condition, in contrast to other tendinopathies around the wrist, carries a significant risk of tendon rupture. Early diagnosis and sometimes urgent operative treatment are necessary to prevent this complication. Localized pain, swelling, and tenderness are the hallmarks of this condition, and similar to other tendinopathies, initial treatment consists of decreased activity and splinting. A short course of oral anti-inflammatory medication can be useful in decreasing symptoms. Diagnostic injections with lidocaine can help to differentiate the condition from other causes of wrist pain, but corticosteroid injections are not routinely used in this condition because of a propensity for the EPL to rupture in chronic cases.

Commonly, a patient may present with a rupture of the EPL without antecedent pain or swelling. There is a well-known association of EPL rupture with fractures of the distal radius that likely occurs owing to a relative “watershed zone” of vascular supply within its tight retinacular sheath. Tendon rupture most often occurs with minimally displaced or nondisplaced fractures and can occur several weeks or months after the original injury.⁸⁷⁻⁹⁰ Individuals with RA and systemic lupus erythematosus are especially prone to rupture of the EPL and other tendons.

Kienböck's Disease

Kienböck's disease is so named for Kienböck,⁹¹ who first described in 1910 what he postulated were avascular changes

in the lunate. Nearly a century later, the cause of this disease remains unclear; it is likely multifactorial. Kienböck's disease should be suspected when a young adult presents with pain and stiffness of the wrist and swelling and tenderness around the region of the dorsal lunate. There is an increased propensity of the disease among patients with an ulna that is anatomically shorter than the radius (so-called ulnar negative variance). Radiographs are needed to confirm and stage the process. Kienböck's disease is staged by the degree of fragmentation and collapse of the lunate, associated osteoarthritis, and carpal collapse in a system originally proposed by Stahl.⁹² In this system, the earliest sign of the disease is a linear or compression fracture in the lunate. Later stages show sclerosis of the lunate, followed by lunate collapse and a loss of carpal height. In the final stage the carpus shows signs of diffuse osteoarthritis with complete collapse and fragmentation of the lunate (Figure 50-5). With the increased sensitivity of MRI, it is possible to identify avascular changes within the lunate before they become evident on plain radiographs. This is referred to as “stage zero” Kienböck's disease.

The treatment for Kienböck's disease is largely surgical. Depending on the stage of the disease and the postulated etiology, several surgical procedures have been described. In early stages of the disease, when there is little lunate collapse and no osteoarthritis, the goal of surgery is to “unload” the lunate by redistributing articular contact forces and allow it to revascularize.⁹³⁻⁹⁶ The most common procedure is a radial shortening osteotomy, performed to neutralize ulnar variance. In later stages, various intercarpal arthrodeses have been used to readjust and maintain carpal height and alignment.⁹⁷⁻⁹⁹ Microsurgical techniques have been used more recently to revascularize the lunate with promising early results.¹⁰⁰

Scapholunate Interosseous Ligament Injury

The interosseous ligament between the scaphoid and the lunate is a stout structure, especially dorsally, and usually

Figure 50-5 Advanced Kienböck's disease, showing carpal collapse, intercarpal and radiocarpal arthrosis, and fragmentation of the lunate. **A**, Posteroanterior view. **B**, Lateral view.

Figure 50-6 Anteroposterior radiograph of the wrist showing scapholunate interosseous space widening (arrow) and scaphoid foreshortening associated with scapholunate interosseous ligament disruption.

requires a significant force to cause disruption. The typical mechanism of injury is a fall onto the outstretched hand with the wrist extended. Early diagnosis is essential to prevent the late sequelae of carpal collapse. The key radiographic features of scapholunate dissociation (scapholunate interval widening) are shown in [Figure 50-6](#). The anteroposterior view shows the scapholunate interval better than the posteroanterior view.¹⁰¹ Early surgical intervention is recommended with the goals of maintaining carpal alignment and preventing an otherwise inevitable progression to carpal collapse and degenerative arthritis.

Gout and Inflammatory Arthritis

All of the inflammatory arthritides including the crystal arthropathies can manifest as dorsal wrist pain. Approximately 25% of patients with a diagnosis of RA present initially with hand and wrist symptoms. The reader is referred to Chapters 94 to 96 for further details.

Wrist Pain: Ulnar

Triangular Fibrocartilage Complex Injury and Ulnocarpal Impaction Syndrome

One of the most complex and confusing areas of the wrist from a diagnostic standpoint is the articulation of the ulna with the carpus. The triangular fibrocartilage complex (TFCC), so named by Palmer and Werner,¹⁰² comprises the articular disk itself and the immediately surrounding ulnocarpal ligaments. It can be injured by a variety of acute and chronic mechanisms. Hyperpronation and hypersupination of the carpus during forceful activities are the usual causes of acute injuries, whereas repetitive pronation and supination more often cause attritional changes in the TFCC. Careful physical examination is important to determine the origin of the pain and to try to discover the maneuver or wrist position that most closely reproduces the symptoms.

The radius and ulna must remain congruent through a 190-degree arc.¹⁰³ Limitation of motion and pain with pronation and supination are consistent with a tear of the supporting ligaments and resultant distal radioulnar joint (DRUJ) instability. If a sufficient portion of the stability has been lost, the ulna appears clinically dislocated or subluxated, and there is severe limitation of forearm rotation. Lateral radiographs of the wrist in neutral and full pronation and supination are not generally specific enough to confirm ulnar subluxation. To evaluate better the congruency of the DRUJ through its range of motion and to assess for subtle subluxations, CT can be performed on both wrists simultaneously in positions of neutral, full pronation, and full supination.¹⁰⁴⁻¹⁰⁷

Tears of the TFCC may manifest with painful clicking during wrist rotation. Patients generally have localized tenderness on the midaxial border of the wrist and directly beneath the extensor carpi ulnaris tendon. If forced ulnar deviation of the wrist or gripping or both reproduce the patient's symptoms, a degenerative tear of the central portion of the TFCC is more likely. The degenerative tear is frequently a component of the ulnocarpal impaction syndrome, a condition associated with higher than normal loads on the ulnar carpus secondary to a congenitally positive ulnar variance.

Plain radiographs are most useful in determining ulnar variance and for ruling out fractures or arthritis as a cause of ulnar wrist pain. Because of the variable relationship of the radius and ulna depending on forearm rotation, it is important to take standardized films when measuring ulnar variance.^{108,109} A posteroanterior view of the wrist with the shoulder abducted to 90 degrees and the elbow flexed to 90 degrees shows the DRUJ in neutral forearm rotation and is easily reproducible ([Figure 50-7](#)). Because the ulna lengthens relative to the radius during power grip, a radiograph in

Figure 50-7 Posteroanterior radiograph of the wrist in neutral forearm rotation showing the method of measuring ulnar variance by drawing tangential lines to the distal ulna and distal radius. The space between these lines in millimeters is the ulnar variance. A positive value indicates the ulnar length is greater than the radial length.

the same position during maximal grip best shows impaction of the ulna on the carpus.

Ancillary studies for TFCC tears include three-compartmental arthrography and MRI. In arthrography, sequential injections of radiopaque dye are performed into the carpal joint, midcarpal joint, and DRUJ. The test is considered positive when the dye is seen leaking from one compartment to another. The site of the leak determines the location of the torn structure.¹¹⁰ Several studies have shown, however, that there are age-related attritional tears, which occur in the TFCC and other ligamentous structures of the wrist.¹¹¹⁻¹¹³ Technologic advancements in MRI have improved the ability to visualize and diagnose abnormalities in the TFCC. MRI can be combined with arthrography to visualize better the TFCC and the intrinsic wrist ligaments. Peripheral detachments and central degenerative tears of the TFCC can be visualized. MRI remains highly operator dependent and technique dependent, and the studies should be interpreted in the context of the findings on physical examination.¹¹⁴

Patients presenting with pain localized to the ulnar side of the wrist often respond to simple splinting and rest. This conservative treatment and NSAIDs can be used effectively while a workup is in progress. A course of rest and splinting, followed by a gradual return to activities, may completely alleviate ulnar-sided symptoms.

Despite the advancements in imaging techniques, there is often no substitute for direct visualization of the ulnocarpal joint or DRUJ or both. Arthroscopy has become an invaluable diagnostic and surgical tool. Tears of the TFCC can be visualized, and their clinical significance better determined. Arthroscopy, done in conjunction with fluoroscopy, can assess for instability of the DRUJ or intercarpal joints or both. Several surgical procedures can now be performed entirely or in part through the arthroscope.^{115,116}

Extensor Carpi Ulnaris Tendinitis and Subluxation

The extensor carpi ulnaris tendon can become irritated with forced pronation/supination activities such as putting topspin on a tennis ball. In severe cases the tendon can begin to sublux around the ulnar head as its restraining dorsal retinaculum becomes increasingly lax. Patients complain of pain with forceful rotation of the forearm, and sometimes there is an associated snapping of the extensor carpi ulnaris tendon. Early treatment consists of immobilization of the wrist and forearm to prevent rotation. Anti-inflammatory medication can help to decrease the inflammation more quickly. After an adequate period of rest, if the acute inflammation resolves, but the extensor carpi ulnaris tendon continues to be unstable, surgery may be indicated to reconstruct or release the sheath at the wrist.

Lunotriquetral Ligament Injury

Tears in the short, stout intraosseous ligament connecting the lunate and the triquetrum are uncommon and often difficult to diagnose. As with the aforementioned diagnoses, patients present with ulnar-sided wrist pain usually worsened by either pronation or supination. Forceful translation of the triquetrum against the lunate causes pain in affected individuals. If diagnosed within 3 to 4 weeks of injury, a

short arm cast allows healing and eliminates symptoms. Chronic tears may lead to advanced carpal instability and collapse. MRI or wrist arthroscopy or both may be necessary to make the diagnosis. Treatment is predicated on the staging of instability and ranges from simple casting for acute instability to ligament reconstruction or intercarpal fusion for more advanced cases.

Pisotriquetral Arthritis

Degenerative changes in the pisotriquetral articulation are usually posttraumatic in nature. Patients may recall a fall onto the extended wrist with direct trauma to the ulnar side of the palm. Affected patients present with pain during passive wrist hyperextension and exacerbation with flexion against resistance. With palpation of the pisotriquetral joint, there is tenderness and often crepitus. As with many joints, splinting, NSAIDs, and occasionally injection with corticosteroid and lidocaine are the mainstays of conservative treatment. If this is inadequate to control the symptoms, surgical resection of the pisiform is indicated.

Wrist Pain: Radial and Base of Thumb

De Quervain's Disease and Intersection Syndrome

One of the most common sites of tendon irritation around the wrist is in the first dorsal extensor compartment, a phenomenon known as de Quervain's disease. The tendons involved are the extensor pollicis brevis and the abductor pollicis longus. At the level of the radial styloid, these two tendons pass through an osteoligamentous tunnel composed of a shallow groove in the radius and an overlying ligament. Anatomic studies have shown that a high percentage of patients have a divided first dorsal compartment, and this can account for failure of conservative treatment and injections.¹¹⁷⁻¹¹⁹

Patients with de Quervain's disease are typically women in their 30s and 40s, although men and women can develop the condition at any age. This is the most common tendinopathy to develop in postpartum women because of the specific hand and wrist position requirements in the care of an infant. Any activity requiring repeated thumb abduction and extension in combination with wrist radial and ulnar deviation can aggravate this problem. Patients complain of pain along the course of these tendons with grasping activities. Clinically, there is tenderness along the affected compartment and there may be swelling over the radial styloid. In severe cases a creaking sound can be elicited with movement of the involved tendons. Finkelstein's test of forced ulnar deviation of the wrist with the thumb clasped in the fist palm is pathognomonic of the condition.^{120,121}

A less common condition that may occur in the same general location in the wrist is intersection syndrome. Although initially attributed to friction between the first and second dorsal compartment tendons, Grundberg and Reagan¹²² subsequently showed that the condition represented a tendinopathy of the radial wrist extensors within the second dorsal compartment.

The primary treatment for de Quervain's disease and intersection syndrome is rest with splinting. For

de Quervain's disease, the wrist should be held in slight extension and the thumb abducted in a thumb spica splint to the level of the interphalangeal joint. Immobilization of the wrist alone, in approximately 15 degrees of extension, is usually adequate for intersection syndrome. The addition of a 2- to 4-week course of anti-inflammatory medication also can be helpful. Phonophoresis with a cortisone cream and injection of the compartment with cortisone are second-line treatments if immobilization alone fails to give adequate relief. Injection of corticosteroid into the affected first dorsal compartment is curative for de Quervain's disease in approximately 75% of patients.¹²³ Surgery may be indicated for patients who do not respond to a course of conservative treatment including injection. For de Quervain's disease and intersection syndrome, surgery consists of releasing the stenotic retinacular sheath of the involved compartment.

Basal Joint Arthropathy

Inflammation and pain related to the carpometacarpal joint of the thumb are common and can occur at any age. In younger patients, instability secondary to ligamentous laxity is associated with joint subluxation and abnormal cartilage wear and may lead to pain with mechanical activities. In women older than 45 years, studies show 25% have radiographic evidence of degeneration of the basal joint.^{124,125} Patients generally present with pain at the base of the thumb, worsened by pinch and highly dexterous activities. They often report difficulty with tasks such as opening jars and bottles, turning doorknobs and keys, and other activities of daily living. The thumb carpometacarpal joint may be swollen and subluxed and is generally tender to palpation. The joint should be assessed for the presence of increased laxity by manual subluxation of the base of the metacarpal out of the trapezial "saddle" with radial and volar force. With advanced degenerative disease, crepitus is sometimes appreciated.

Radiographs should be obtained to determine the stage of the disease. The addition of a basal joint posteroanterior stress film, in which the patient presses the tips of the thumbs together firmly with the nail plates facing up, is helpful in assessing joint subluxation (Figure 50-8). The

Figure 50-8 "Basal joint stress" radiograph showing stage 3 degeneration of the left thumb and stage 4 degeneration of the right thumb.

Figure 50-9 Typical hand-based custom-molded splint used in the treatment of symptomatic basal joint arthritis. The thumb interphalangeal joint and wrist are left free to improve the patient's function while wearing the splint.

most commonly used staging system was developed by Eaton and Glickel¹²⁶ and is based on the degree of involvement of the trapeziometacarpal joint and whether or not the scaphotrapezoid joint is involved.¹²⁶ Advancing stages show increased subluxation of the basal joint, with development of joint space narrowing, osteophytes, and subchondral cysts.

Regardless of the stage of the disease, the first line of treatment is immobilization of the thumb metacarpal, leaving the interphalangeal joint free. Splinting has been shown to alleviate the symptoms of carpometacarpal joint inflammation in more than 50% of patients.¹²⁷ NSAIDs can be a useful adjunct. Injections of corticosteroid are effective, usually for just a limited time. Although therapy for thenar muscle strengthening has been advocated, especially in early stages, its benefits are minimal and it can occasionally aggravate the problem.

Many patients are able to manage their symptoms with a combination of splinting, medications, corticosteroid injections, and activity modification. The most effective splints are those that are custom made of a moldable plastic material. They may be hand based as shown in Figure 50-9 or forearm based to immobilize the wrist as well. If these various nonoperative treatments are insufficient, surgery may be indicated in young patients to reconstruct the ligaments that stabilize the metacarpal base. In patients with advanced degenerative changes and whose symptoms continue to interfere sufficiently with their daily activities, surgery is indicated to replace the joint with a prosthetic device or to excise the trapezium and reconstruct the soft tissue supports.

Volar Ganglion

Another common location for ganglia is the radial side of the volar wrist. Ganglia typically originate from the scaphotrapezial joint but become superficial and are clinically evident at or near the distal wrist crease over the flexor carpi radialis tendon. Volar ganglia can occur in close proximity to the radial artery and should be differentiated from a radial artery aneurysm. Aspiration, if attempted, should be performed carefully to avoid vascular injury, and surgery should be preceded by performance of an Allen test to document patent ulnar arterial flow. Volar ganglia are associated with a higher recurrence rate and a higher complication rate than their dorsal counterparts.¹²⁸

Scaphoid Fracture and Nonunion

Occasionally, a young or middle-aged patient presents with a nonunited scaphoid fracture without recollection of a traumatic incident. When evaluating a relatively young patient with pain at the base of the thumb, wrist swelling in the region of the anatomic snuffbox, and a decreased range of motion of the wrist, plain radiographs and a specialized ulnar-deviation “navicular” radiograph should be obtained to rule out scaphoid pathology. In patients in whom a scaphoid nonunion has been present for a significant period, secondary changes in carpal alignment and joint degeneration have usually occurred. Although splint or cast immobilization can be tried, surgical repair of the scaphoid or other wrist salvage procedure is usually required.

Palm

Trigger Finger

Painful clicking and locking of the digits in flexion is one of the most common causes of pain in the hand. This condition, caused by a thickening of the A1 retinacular pulley in the palm, is commonly known as *trigger finger*. The thumb is the most commonly affected digit, followed by the ring and long fingers.¹²⁹ Patients may present with isolated activity-related pain in the proximal interphalangeal joint without frank clicking or locking. Early clicking is felt as a snapping sensation during digital motion and is frequently worse on awakening. As the condition progresses, the digital range of motion can be reduced and secondary proximal interphalangeal joint contractures develop. The final stage is a locked trigger finger that cannot be straightened actively.

Primary trigger finger is the most common type, found most often in middle-aged individuals. Triggering of the thumb is four times more frequent in women than in men.⁵ Secondary triggering is seen in association with such diseases as RA, diabetes, and gout. In this type, trigger fingers are often multiple and can coexist with other stenosing tendinopathies such as de Quervain's disease or CTS. Congenital or developmental triggering can be identified in children and is much less common. Similar to its presentation in adults, the thumb is most commonly affected, but in contrast to adults, triggering often presents with the interphalangeal joint locked in flexion.

Figure 50-10 Technique for injecting a trigger finger. The solid line denotes the distal palmar crease. The dashed line indicates the midline of the digit. The needle enters at an angle of between 45 and 60 degrees.

Nonoperative treatment of this condition consists primarily of splinting and local steroid injections. Splinting is most effective at night to prevent the digit from locking. In adults, injection of steroid into the tendon sheath has been shown to be quite effective (Figure 50-10).^{5,6,130} Injection is used infrequently in infants or children. When nonoperative treatments fail to give lasting relief, surgical treatment consists of longitudinal division of the A1 pulley at the level of the metacarpal head. It is a simple procedure that yields reliable and permanent results with few complications.

Retinacular Cysts

Retinacular ganglion cysts can occur in conjunction with a triggering digit or in isolation. They are located at the base of the digit over the A1 pulley as a discrete, firm, pea-sized nodule. They originate from the flexor tendon sheath or annular pulleys and contain synovial fluid. Patients usually complain of pain with gripping objects or with direct pressure over the cyst. A retinacular cyst is most easily treated initially by needle decompression, with care to avoid injury to the sensory nerves that lie immediately adjacent to the flexor tendon and associated cyst. Approximately 50% recur after aspiration, and surgical resection may be required.

Digits

Mallet Finger

Mallet finger refers to a loss of terminal extension of the distal interphalangeal joint of the digit and can be classified as bony or soft tissue depending on where the disruption in the extensor mechanism occurred. Mallet fingers can occur with minimal trauma such as tucking in bed sheets and may not be recalled by the patient. This sometimes leads to a delay in diagnosis and treatment. When a patient presents with a digit that droops at the distal interphalangeal joint and cannot be actively extended, but has full passive motion, a radiograph should be obtained to determine if there is an associated fracture of the distal phalanx. An extension splint is the treatment of choice for bony and soft

tissue mallet fingers. The distal interphalangeal joint should be held in full extension, and care should be taken not to force the distal interphalangeal joint into hyperextension to prevent dorsal skin ischemia and necrosis. Splinting is employed full time for 6 weeks. The patient should not remove the splint for showering or any other activity but may change the splint carefully for skin care, provided that the joint is maintained in extension throughout. Proximal interphalangeal flexion exercises are initiated from the outset and are important to help reset the tension in the extensor mechanism. Gentle distal interphalangeal flexion exercises are begun at 6 weeks, and splinting is decreased to nighttime between 6 and 8 weeks. Patients usually can expect a small extension lag, on the order of 5 degrees, and a return of most of their flexion.

Osteoarthritis of the Digits

Osteoarthritis of the interphalangeal joints is extremely common in older patients and is most often manifested as Heberden's nodes of the distal interphalangeal joint. Despite gross deformities, pain and dysfunction may be minimal. A mucous cyst may appear in association with degenerative arthritis. Mucous cysts appear on the dorsum of the joint and can cause nail growth deformities owing to pressure on the germinal matrix (Figure 50-11). The changes in nail growth may precede clinical detection of the cyst. These cysts should not be aspirated with a needle because of the close proximity of the distal interphalangeal joint and the risk of secondary joint infection. Treatment consists of distal interphalangeal joint immobilization to control symptoms or surgical excision of the cyst and in particular the underlying osteophytic spurs.

Tumors

Benign bone tumors such as simple bone cysts and enchondromas are common in the phalanges. These usually cause

no symptoms and frequently are diagnosed as incidental findings on routine hand radiographs. Enchondromas are most commonly located in the metaphysis of the proximal phalanx and may lead to fracture with minimal trauma as a result of weakening of the bone structure. If a pathologic fracture occurs, nonoperative treatment is indicated until the fracture heals. The bone tumor subsequently can be addressed with curettage and bone grafting. Occasionally, because of malalignment, earlier surgical intervention becomes necessary.

Many soft tissue tumors can occur in the hand and digits. Some common benign tumors are giant cell tumors of the tendon sheath, lipomas, and glomus tumors. Lipomas and giant cell tumors of the tendon sheath manifest clinically as painless, slow-growing masses in the palm and digits. Surgical excision is necessary for diagnosis. Glomus tumors arise from the pericytes in the fingertip or subungual area and typically present with intermittent sharp pain in the fingertip. These vascular tumors become intensely symptomatic when the hand is exposed to cold temperatures, owing to abnormal arteriovenous shunting through the hypertrophic glomus system. Surgical excision is generally curative and should be preceded by MRI to rule out multifocal sites.

Infection

The most common infection in the hand is the paronychia. It involves the fold of tissue surrounding the fingernail. *Staphylococcus aureus* is the usual pathogen, introduced by a hangnail, a manicure instrument, or nail biting. Patients present with an exquisitely painful and erythematous swelling involving a part of the nail fold. Occasionally, the infection can progress to surround the nail in a horseshoe fashion and undermine the nail plate. If seen early, within the first 24 to 48 hours, oral antibiotics and local treatment of the finger with warm soaks can be effective. Superficial abscesses can be drained with a sharp blade through the thin skin without requiring local anesthesia. Larger or more chronic infections require surgical drainage.

An infection of the distal pulp of the fingertip, known as a *felon*, is a particular problem in diabetic patients. This infection differs from other subcutaneous infections because of the vertical fibrous septa that divide and stabilize the pulp of the fingertip. Often patients have had some recent penetrating injury in the area. Because of the tightly constrained area of the infection, patients present with an intensely painful fingertip. There may be an area of "pointing" over the abscess. Surgical drainage is required followed by soaks and oral antibiotics, and intravenous antibiotics are generally recommended in diabetic patients.

Although similar in appearance to a paronychia, herpetic whitlow is caused by herpes simplex virus and must be differentiated from other fingertip infections because of a radically different treatment protocol.^{131,132} Whitlow was common among dental hygienists before the widespread use of gloves for all health care workers. As with bacterial infections, the area becomes painful and erythematous; local tenderness is much less severe, however. Diagnosis is by clinical presentation and history. If seen early, vesicles can be ruptured for fluid analysis and viral culture. Nonoperative treatment with oral antiviral agents is recommended.

Figure 50-11 Dorsal view of a digit with an as yet clinically inapparent mucous cyst and the corresponding groove deformity of the nail plate.

Other hand and digit infections such as suppurative flexor tenosynovitis, deep space infections of the palm, pyogenic arthritis, infections from bite wounds, and osteomyelitis should be evaluated initially with radiographs of the hand and appropriate blood work. If possible, antibiotics should be withheld until definitive cultures are obtained from the affected area. Antibiotics should be administered intravenously, and the hand and wrist should be immobilized. Most infections of this nature require surgical drainage for definitive treatment.

KEY POINTS

Temporomandibular joint (TMJ) pain must be distinguished from the pain that more commonly arises from the muscles of mastication (myofascial pain), which can produce similar signs and symptoms.

TMJ pain also must be distinguished from pain coming from the ear or parotid gland.

TMJ pain and masticatory muscle pain generally are accompanied by limitation of mouth opening, but not pain arising from the ear or parotid gland.

Most major systemic arthropathies may also involve the TMJ and thereby give rise to pain and limited jaw movement.

Displacement of the intra-articular disk in the TMJ produces pain that is accompanied by a clicking or popping sound or sudden onset of jaw locking.

Pain in the temporomandibular joint (TMJ) region, a commonly encountered symptom, affects more than 10 million Americans. Because of its diverse causes, however, considerable difficulty is often involved in proper diagnosis and treatment. Owing to the proximity of the ear and parotid gland and the similar nature of pain in these areas, pathologic conditions involving these structures are often confused with conditions arising in the TMJ. Pain occurring in the adjacent muscles of mastication, also a frequently encountered situation, not only is similar to TMJ pain in character and location, but also is associated with jaw dysfunction, a common finding with painful conditions directly involving the TMJ. For these reasons, knowledge of the various painful conditions occurring in the TMJ region is essential in establishing a correct diagnosis.

Because patients with primary TMJ disease often have secondary myofascial pain in the muscles of mastication, and because patients with primary myofascial pain problems in the masticatory muscles can develop secondary TMJ disease, the generally accepted term used to describe this overlapping group of conditions is *temporomandibular disorders*. These conditions are subdivided for purposes of diagnosis and treatment into conditions that primarily involve the TMJ (TMJ problems) and conditions that primarily involve the muscles of mastication (myofascial pain and dysfunction [MPD], masticatory myalgia). From a diagnostic standpoint, it is important to consider the numerous conditions that mimic the temporomandibular disorders or MPD by producing similar signs and symptoms (Tables 51-1 and 51-2).

Table 51-3 lists the various pathologic entities that commonly involve the TMJ. Although a variety of conditions

Temporomandibular Joint Pain

DANIEL M. LASKIN

are known, only three types are considered to generally produce pain: the various arthritides, derangements of the intra-articular disk, and certain neoplasms.

ARTHRITIS OF THE TEMPOROMANDIBULAR JOINT

Arthritis is the most common painful condition affecting the TMJ. Although osteoarthritis and rheumatoid arthritis are encountered most frequently, cases of infectious arthritis, metabolic arthritis, and presentation as part of the spondyloarthropathies are also seen in practice. Traumatic arthritis is another relatively common occurrence.

Osteoarthritis

Osteoarthritis is the most common type of arthritis involving the TMJ and the most frequent cause of pain in that region. Clinical symptoms of the disease have been reported in 16% of the general population,¹ but radiographic features have been found in 44% of asymptomatic individuals.² Although the TMJ is not a weight-bearing joint in the same sense as the joints of the long bones, the stresses associated with such parafunctional habits as clenching and grinding of the teeth are sufficient to contribute to similar degenerative changes in some patients.³ Acute and chronic trauma and derangements of the intra-articular disk also are common causes of secondary degenerative arthritis.

Clinical Findings

Primary osteoarthritis, which usually is seen in older individuals, is insidious in its onset; it generally produces only mild discomfort, and individuals rarely complain about the condition. Secondary osteoarthritis usually occurs in younger patients (20 to 40 years old) and tends to be painful. In contrast to primary degenerative joint disease and rheumatoid arthritis, it often is limited to only one TMJ, although it may become bilateral in the late stages, and involvement of other joints is uncommon. The condition is characterized by TMJ pain that is increased by function, joint tenderness, limitation of mouth opening, and occasional clicking and popping sounds. In the late stages, crepitation may be noted in the joint.

Imaging Findings

The earliest radiologic feature of osteoarthritis of the TMJ, whether primary or secondary, is subchondral sclerosis in the mandibular condyle. If the condition progresses,

Table 51-1 Differential Diagnosis of Nonarticular Conditions Mimicking Temporomandibular Joint Pain or Myofascial Pain in the Masticatory Muscles

Disorder	Jaw Limitation	Muscle Tenderness	Diagnostic Features
Pulpitis	No	No	Mild to severe ache or throbbing; intermittent or constant; aggravated by thermal change; eliminated by dental anesthesia; positive radiographic findings
Pericoronitis	Yes	Possible	Persistent mild to severe ache; difficulty swallowing; possible fever; local inflammation; relieved with dental anesthesia
Otitis media	No	No	Moderate to severe earache; constant pain; fever; usually history of upper respiratory infection; no temporomandibular joint tenderness
Parotitis	Yes	No	Constant aching pain, worse when eating; pressure feeling; absent salivary flow; ear lobe elevated; suppuration from duct
Sinusitis	No	No	Constant aching or throbbing; worse with change of head position; nasal discharge; often maxillary molar pain not relieved by dental anesthesia
Trigeminal neuralgia	No	No	Sharp stabbing pain of short duration; trigger zone; pain follows nerve pathway; older age group; often relieved by dental anesthesia
Atypical (vascular) neuralgia	No	No	Diffuse throbbing or burning pain of long duration; often associated autonomic symptoms; no relief with dental anesthesia
Temporal arteritis	No	No	Constant throbbing preauricular pain; artery prominent and tender; low-grade fever; may have visual problems; elevated erythrocyte sedimentation rate
Trotter's syndrome	Yes	No	Aching pain in ear, side of face, and lower jaw; deafness; nasal obstruction; cervical lymphadenopathy
Eagle's syndrome	No	No	Mild to sharp stabbing pain in ear, throat, and retromandible; provoked by swallowing, turning head, carotid compression; usually post tonsillectomy; styloid process >2.5 cm

Modified from Laskin DM, Block S: Diagnosis and treatment of myofascial pain dysfunction (MPD) syndrome, *J Prosthet Dent* 56:75–84, 1986.

condylar flattening and marginal lipping may be noted. In the later stages, erosion of the cortical plate, osteophyte formation, or both may occur. Breakdown of the subcortical bone occasionally may result in the formation of bone cysts. Although changes in the articular fossa generally are not as severe as changes in the condyle, cortical erosion sometimes

can be seen. Narrowing of the joint space also occurs in the late stages; this is indicative of concomitant degenerative changes in the intra-articular disk. Although changes in the TMJ usually can be seen on plain radiographs, sagittal and coronal computed tomography (CT) scans are the preferred modality for imaging the bony structures.

Table 51-2 Differential Diagnosis of Nonarticular Conditions Producing Limitation of Mandibular Movement

Disorder	Jaw Limitation	Muscle Tenderness	Diagnostic Features
Odontogenic infection	Yes	Yes	Fever; swelling; positive radiographic findings; tooth tender to percussion; pain relieved and movement improved with dental anesthesia
Nonodontogenic infection	Yes	Yes	Fever; swelling; negative dental findings on radiograph; dental anesthesia may not relieve pain or improve jaw movement
Myositis	Yes	Yes	Sudden onset; jaw movement associated with pain; areas of muscle tenderness; usually no fever
Myositis ossificans	No	No	Palpable nodules seen as radiopaque areas on radiograph; involvement of nonmasticatory muscles
Neoplasia	Possible	Possible	Palpable mass; regional nodes may be enlarged; may have paresthesia; radiograph may show bone involvement
Scleroderma	No	No	Skin hard and atrophic; mask-like facies; paresthesias; arthritic joint pain; widening of periodontal ligament
Hysteria	No	No	Sudden onset after psychological trauma; no physical findings; jaw opens easily under general anesthesia
Tetanus	Yes	No	Recent wound; stiffness of neck; difficulty swallowing; spasm of facial muscles; headache
Extrapyramidal reaction	No	No	Patient on antipsychotic drug or phenothiazine tranquilizer; hypertonic movement; lip smacking; spontaneous chewing motions
Depressed zygomatic arch	Possible	No	History of trauma; facial depression; positive radiographic findings
Osteochondroma coronoid	No	No	Gradual limitation; jaw may deviate to unaffected side; possible clicking sound on jaw movement; positive radiograph findings

Modified from Laskin DM, Block S: Diagnosis and treatment of myofascial pain dysfunction (MPD) syndrome, *J Prosthet Dent* 56:75–84, 1986.

Diagnosis

The diagnosis of osteoarthritis is based on the patient's history and clinical and radiographic findings. A history of trauma or parafunctional oral habits is often reported. Involvement is generally unilateral, and no significant changes are observed in any of the other joints. The pain tends to be well localized, and the TMJ is often tender to palpation.

Treatment

Treatment of degenerative arthritis of the TMJ is usually medical, as in other joints of the body. It involves the use of nonsteroidal anti-inflammatory drugs, application of heat, eating a soft diet, limitation of jaw function, and use of a bite appliance to control parafunction if the patient has a chronic habit of clenching or grinding the teeth. Arthrocentesis has also been shown to be helpful.^{4,5} Physical therapy with thermal agents, ultrasound, and iontophoresis also can be beneficial, and isotonic and isometric exercises are used to improve joint stability after acute symptoms have subsided. The use of intra-articular steroid injections is controversial; they should be used only in patients with acute symptoms that do not respond to other forms of medical management. Because of the potentially damaging effects of long-acting steroids,^{4,6} they should be limited to no more than three or four single injections given at 3-month intervals. Intra-articular injection of high-molecular-weight sodium hyaluronate given twice, 2 weeks apart, has been shown to have essentially the same therapeutic effect as a steroid injection, without the potential adverse effects.^{5,7}

When the acute symptoms have been controlled, therapy is directed toward control of factors possibly contributing to the degenerative process. Unfavorable loading of the joint is eliminated by replacement of missing teeth to establish a good, functional occlusion; by correction of any severe dental malrelationships through orthodontics or orthognathic surgery; and by continued use of a bite appliance at night to control teeth-clenching or teeth-grinding habits.^{6,8}

In patients in whom medical management for 3 to 6 months fails to relieve the symptoms, surgical management may be indicated. Surgery involves removal of only the minimal amount of bone necessary to produce a smooth articular surface. Unnecessary removal of the entire cortical plate, as occurs with the so-called condylar shave procedure or high condylotomy, can lead to continuation of the resorptive process in some instances, and should be avoided if possible.

Rheumatoid Arthritis

More than 50% of patients with rheumatoid arthritis have involvement of the TMJ.⁹ Although the TMJ may be affected early in the course of the disease, other joints in the body usually are involved first. The general female-to-male ratio is 3:1. TMJ involvement may also characterize juvenile inflammatory arthritis. In children, destruction of the mandibular condyle by the disease process results in growth retardation and facial deformity characterized by a

severely retruded chin. Fibrous or bony ankylosis is a possible sequel at all ages.

Clinical Findings

Patients with rheumatoid arthritis of the TMJ have bilateral pain, tenderness, swelling in the preauricular region, and limitation of mandibular movement. These symptoms are characterized by periods of exacerbation and remission. Joint stiffness and pain are usually worse in the morning and decrease during the day. The limitation in mandibular movement worsens as the disease progresses; the patient also may develop an anterior open bite.

Imaging Findings

Although radiographic changes may not be noted in the early stages of the disease, about 50% to 80% of patients show bilateral evidence of demineralization, condylar flattening, and bone erosion as the disease progresses, so the articular surface appears irregular and ragged. Erosion of the glenoid fossa also is seen sometimes. Narrowing of the joint space is caused by destruction of the intra-articular disk. With continued destruction of the condyle, loss of ramus height can lead to contact of only the posterior teeth and an anterior open bite.

Diagnosis

Rheumatoid arthritis is diagnosed on the basis of the history, clinical and radiographic findings, and confirmatory laboratory tests. Distinguishing features for rheumatoid arthritis and degenerative arthritis of the TMJ are shown in Table 51-3.

Treatment

Treatment of rheumatoid arthritis of the TMJ is similar to that provided for other joints.^{7,10} Anti-inflammatory drugs are used during the acute phases, and mild jaw exercises are used to prevent excessive loss of motion when acute symptoms subside. In severe cases, disease-modifying drugs, such as methotrexate, and biologic agents, including etanercept, infliximab, adalimumab, certolizumab, golimumab, abatacept, tocilizumab, and rituximab, may be used pending systemic presentation. Orthognathic surgery may be necessary in patients with an anterior open bite after the disease goes into remission, or in patients in whom ankylosis develops after that condition is corrected.

Spondyloarthropathies

In addition to the adult and juvenile forms of rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, and reactive arthritis also can involve the TMJ.⁸⁻¹³

Psoriatic Arthritis

Psoriatic arthritis occurs in approximately one-third of patients who have cutaneous psoriasis. It can have a sudden onset, can be episodic in nature, and may show spontaneous

Table 51-3 Differential Diagnosis of Temporomandibular Joint (TMJ) Diseases

Disorder	Jaw Limitation	Muscle Tenderness	Diagnostic Features
Agenesis	No	Yes	Congenital; usually unilateral; mandible deviates to affected side; unaffected side long and flat; severe malocclusion; often ear abnormalities; radiograph shows condylar deficiency
Condylar hypoplasia	No	No	Congenital or acquired; affected side has short mandibular body and ramus, fullness of face, deviation of chin; body of mandible elongated and face flat on unaffected side; malocclusion; radiograph shows condylar deformity, antegonial notching
Condylar hyperplasia	No	No	Facial asymmetry with deviation of chin to unaffected side; cross-bite malocclusion; prognathic appearance; lower border of mandible often convex on affected side; radiograph shows symmetric enlargement of condyle
Neoplasia	Possible	Yes	Mandible may deviate to affected side; radiographs show enlarged, irregularly shaped condyle or bone destruction, depending on type of tumor; unilateral condition
Infectious arthritis	Yes	No	Signs of infection; may be part of systemic disease; radiograph may be normal early, later can show bone destruction; fluctuance may be present; pus may be obtained on aspiration; usually unilateral
Rheumatoid arthritis	Yes	Yes	Signs of inflammation; findings in other joints (hands, wrists, feet, elbows, ankles); positive laboratory test results; retarded mandibular growth in children; anterior open bite; radiograph shows bone destruction; usually bilateral
Spondyloarthropathies Psoriatic arthritis	Yes	Yes	Presence of cutaneous psoriasis; nail dystrophy; involvement of distal interphalangeal joints; radiograph shows condylar erosion; negative for rheumatoid factor
Ankylosing spondylitis	Yes	Yes	Frequent involvement of the spine and sacroiliac joint; extra-articular manifestations of spondylitis include iritis, anterior uveitis, aortic insufficiency, and conduction defects; erosive condylar changes; TMJ ankylosis may occur
Metabolic arthritis Gout	Yes	Yes	Usually sudden onset; often monoarticular; commonly involves great toe, ankle, and wrist; joint swollen, red, and tender; increased serum uric acid; late radiographic changes
Pseudogout	Yes	Yes	Generally unilateral; TMJ may be only joint involved; joint frequently swollen; presence of intra-articular calcification; may be a history of trauma
Traumatic arthritis	Yes	Yes	History of trauma; radiograph normal except for possible widening of joint space; local tenderness; usually unilateral
Degenerative arthritis	Yes	Yes	Unilateral joint tenderness; often crepitus; TMJ may be only joint involved; radiograph may be normal or show condylar flattening, lipping, spurring, or erosion
Ankylosis	No	Yes	Usually unilateral, but can be bilateral; may be history of trauma; young patient may show retarded mandibular growth; radiographs show loss of normal joint architecture
Internal disk degeneration	Yes	Yes	Pain exacerbated by function; clicking on opening or opening limited to <25 mm with no click; positive magnetic resonance imaging findings; may be history of trauma; usually unilateral

Modified from Laskin DM, Block S: Diagnosis and treatment of myofascial pain dysfunction (MPD) syndrome, *J Prosthet Dent* 56:75–84, 1986.

remission.^{9,12} Often only one TMJ is involved. Symptoms include TMJ pain and tenderness, restricted jaw movement, and crepitation, mimicking the symptoms of rheumatoid arthritis.^{9,12} Radiographic changes are nonspecific and cannot be distinguished easily from those of other types of arthritis, particularly rheumatoid arthritis and ankylosing spondylitis.^{13,14} They usually involve erosive changes in the condyle and glenoid fossa associated with extreme narrowing of the joint space.^{11,15,16} In severe cases, ankylosis may develop, reflected occasionally in new bone formation at earlier stages.^{12,17}

The diagnosis usually is based on the triad of psoriasis, radiographic evidence of erosive arthritis, and a negative serologic test for rheumatoid factor. Even in the presence of a rash, however, the diagnosis cannot be absolutely confirmed. The differential diagnosis always should include

rheumatoid arthritis, reactive arthritis, ankylosing spondylitis, and gout.

Treatment of psoriatic arthritis of the TMJ is similar to that of rheumatoid arthritis, and is driven essentially by the imperative to treat the systemic inflammatory disease process.^{13,18-21} Surgery is necessary if ankylosis occurs.

Ankylosing Spondylitis

About one-third of patients with ankylosing spondylitis develop TMJ involvement several years after onset of the disease. Pain and limitation of jaw movement are the most common symptoms, and ankylosis can develop in advanced cases.^{8,11,14,22} On radiographic examination, about 30% of patients show erosive changes in the condyle and fossa and narrowing of the joint space.^{15,23} In long-standing cases, a

more florid osteophytic response is sometimes seen during quiescent periods. The severity of the changes seems to be related to the severity of the disease. Treatment of ankylosing spondylitis of the TMJ is generally medical and is part of the total management of the patient. Physical therapy is used to improve jaw mobility, and bite appliances are used, when indicated, to reduce parafunctional stress on the joint. If ankylosis develops, surgery is the treatment of choice.²⁴

Reactive Arthritis

Reactive arthritis of the temporomandibular joint is more common in males than in females. It is characterized by recurrent pain, swelling, and limitation of mouth opening.²⁵ Radiographically, condylar erosion may be evident.²⁶ Treatment is similar to that of the other seronegative spondyloarthropathies, consisting of nonsteroidal anti-inflammatory drugs, intra-articular steroids, and disease-modifying drugs. If a specific triggering bacterial infection can be identified, an appropriate antibiotic should be prescribed.

Traumatic Arthritis

Acute trauma to the mandible that does not result in a fracture can still produce injury to the TMJ. When this occurs in a child, it is essential to warn the parents about the possibility of future retardation of mandibular growth and associated facial deformity resulting from damage to the articular cartilage, which is an important growth site.^{16,27}

Traumatic arthritis is characterized by TMJ pain and tenderness and limitation of jaw movement. The resultant inflammation and occasional hemarthrosis can lead to loss of tooth contact on the affected side. Frequently, bruises or lacerations are apparent at the site of the initial injury. No radiographic changes may be seen, or widening of the joint space may be produced by intra-articular edema or hemorrhage. In some instances, radiographs may show an intra-capsular fracture that was not recognized on clinical examination.

Treatment of traumatic arthritis consists of the use of nonsteroidal anti-inflammatory drugs, application of heat, a soft diet, and initial restriction of jaw movement. When acute symptoms subside, range-of-motion exercises should be used to avoid fibrous ankylosis.

Infectious Arthritis

Infectious arthritis rarely involves the TMJ. Although it can affect the joint as part of such systemic diseases as gonorrhea, syphilis, tuberculosis, and Lyme disease,^{17,18,28,29} the most common way is by direct extension of an adjacent infection of dental, parotid gland, or otic origin.^{19,30} Occasionally, it also may occur from localization of blood-borne organisms in the joint after a traumatic injury or by direct involvement through a penetrating wound.^{20,30} The most common pathogens are *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus* species.³¹

Clinical Findings

Infectious arthritis generally results in unilateral pain, tenderness, swelling, and redness in the region of the TMJ.

Chills, fever, sweating, and systemic findings characteristic of the specific type of infection also are present. Often the teeth cannot be occluded because of swelling within the joint. In pyogenic forms of infectious arthritis, fluctuation may be noted in the joint region. Patients with Lyme disease show characteristic skin lesions and often positive serology.^{18,29}

Imaging Findings

Radiographic findings are usually normal in early stages of the disease because of lack of bony involvement, but the intra-articular accumulation of pus or inflammatory exudate may cause separation of articulating surfaces, which can be detected on magnetic resonance imaging (MRI). Later, depending on the severity and chronicity of the infection, varying degrees of bony destruction, ranging from damage to the articular surface of the mandibular condyle to extensive osteomyelitis, may be seen. In the late stages, fibrous or bony ankylosis may occur. In children, infectious arthritis can affect growth of the condyle, resulting in facial asymmetry.

Treatment

Treatment of infectious arthritis includes the use of appropriate antibiotics, proper hydration, control of pain, and limitation of jaw movement. Arthrocentesis with Ringer's solution one to three times weekly until acute symptoms subside has also been recommended.³² Suppurative infections may require aspiration, incision, and drainage, or sequestrectomy. When bone loss has been extensive, reconstructive procedures may be necessary. In children in whom mandibular growth has been affected, a costochondral graft can be used to correct facial asymmetry and re-establish growth of the mandible.

Metabolic Arthritis

Metabolic arthritis, which can accompany gout or pseudogout (calcium pyrophosphate dehydrate arthropathy), is rare in the TMJ.^{21,33}

Gout

Gouty arthritis of the TMJ occurs most frequently in men older than 40 years and usually is preceded by involvement of one or more joints of the feet or hands. The attack usually occurs suddenly, and the joint becomes swollen, painful, red, and tender. Recovery may occur in a few days, and remission can last for months to years.

When attacks are infrequent, radiographic changes may not be noted for a long time. Because so few cases have been reported, the precise radiographic changes that occur have not been well documented. Calcified areas in the disk, destruction of the hard tissues of the joint, condylar exostoses and spurring, and the presence of tophi have been described.^{21,33-35} The initial approach to treatment of gout involving the TMJ is medical. If symptoms are not controlled, however, surgical débridement of the joint and arthroplasty may be indicated.

Pseudogout

Calcium pyrophosphate dehydrate arthropathy (pseudogout) in the TMJ clinically mimics gout, and the mandibular condyle may show degenerative and erosive changes radiographically. In the primary form, which usually is seen in older patients, intra-articular calcification is noted (chondrocalcinosis), and diffuse calcification occurs in the intra-articular disk.^{21-25,36-39} Similar changes are seen in the secondary form, but it occurs in younger patients and frequently is preceded by a history of trauma. Just as in gout of the TMJ, the initial treatment of pseudogout is medical, and surgery is reserved for patients in whom such treatment is ineffective.

INTERNAL DERANGEMENTS

Internal derangements are a common cause of pain in the TMJ. They represent a disturbance in the normal anatomic relationship between the intra-articular disk and the condyle, resulting in interference with the smooth movement of the joint.

Clinical Findings

Three stages of internal derangement have been identified: (1) a painless incoordination phase, in which a momentary catching sensation is felt during mouth opening; (2) anterior disk displacement with reduction into the normal position during mouth opening, which is characterized by a clicking or popping sound (Figure 51-1); and (3) anterior disk displacement without reduction on attempted mouth

Figure 51-1 Anterior displacement of the intra-articular disk with reduction on opening of the mouth. A clicking or popping sound occurs as the disk returns to its normal position in relation to the condyle. During closure, the disk again becomes anteriorly displaced, sometimes accompanied by a second sound (reciprocal click). (Modified from McCarty W: *Diagnosis and treatment of internal derangements of the articular disc and mandibular condyle*. In Solberg WK, Clark GT, editors: *Temporomandibular joint problems: biologic diagnosis and treatment*, Chicago, 1980, Quintessence, p 155.)

Figure 51-2 A-E, Anterior displacement of the intra-articular disk without reduction on attempted mouth opening. The displaced disk acts as a barrier and prevents full translation of the condyle. (Modified from McCarty W: *Diagnosis and treatment of internal derangements of the articular disc and mandibular condyle*. In Solberg WK, Clark GT, editors: *Temporomandibular joint problems: biologic diagnosis and treatment*, Chicago, 1980, Quintessence, p 151.)

opening, which is characterized by restriction of jaw movement, or locking (Figure 51-2). Joint pain in patients with anterior disk displacement, with or without reduction, is caused by condylar compression of the highly innervated retrodiskal tissue that occupies the glenoid fossa as the intra-articular disk assumes a more forward position, and by the accompanying inflammation.

Etiology

The three main causes of internal derangement of the intra-articular disk are trauma, abnormal functional loading of the joint, and degenerative joint disease.^{26,40} It has been suggested that spasm in the lateral pterygoid muscle, a portion of which attaches to the anterior aspect of the disk, can lead to a disk derangement, but evidence for this theory is circumstantial. Although some clinicians believe that occlusal factors also play a role in causing internal derangements, no conclusive studies have shown such a relationship.

Acute macrotrauma is probably the most common cause of internal derangement. Among the incidents that have been implicated are a blow to the jaw, endotracheal intubation, cervical traction, and iatrogenic stretching of the joint during dental or oral surgical procedures. Although whiplash injuries frequently have been implicated in the development of internal derangement, a study of 155 patients with this type of injury showed that only 1 developed clicking in the TMJ immediately after the automobile accident.^{27,41} At 1 month of follow-up, two additional patients of the 129 contacted experienced clicking, but at 1 year, no additional patients of the 104 contacted had developed clicking. Although internal derangements of the TMJ can be caused by a whiplash injury, the incidence seems to be low.

Whether a patient merely develops alterations in the articular surface leading to a catching or binding sensation, anterior disk displacement with reduction on mouth opening (clicking or popping), or anterior disk displacement without reduction during mouth opening (locking) after trauma to the TMJ depends on the severity of the injury. Although associated traumatic arthritis causes pain during function in each of these instances, the pain is more severe in the last two conditions because of compression of retrodiskal tissue, which is now located in the articular zone.

Functional overloading of the TMJ associated with the habit of chronic teeth clenching is another frequent cause of internal derangements. Although the TMJ is constructed for eccentric movements, it is not constructed for the constant isometric loading and unloading that occurs during this activity. Such parafunction affects the lubrication of the joint and alters the articular surfaces, introducing friction between the disk and the condyle that leads to degenerative changes in the articular surfaces and results in gradual anterior displacement of the disk.^{26,28,40,42}

Degenerative joint disease may precede the development of an internal derangement, or it may occur after the development of an internal derangement. In the first instance, changes in the character of the articulating surfaces result in an inability of the parts to glide smoothly over each other, gradually leading to forward displacement of the disk, which normally rotates posteriorly during mouth opening. In the second instance, the displaced disk results in an altered relationship between articulating components of the joint, which leads to degenerative changes in these structures. In patients in whom the condition causing the degenerative joint disease is still active, whether primarily or secondarily, the condition and the disk derangement must be treated for the problem to be resolved completely.

Imaging Findings

Depending on the cause of the internal derangement and its duration, radiographs may or may not show any evidence of degenerative joint disease. Magnetic resonance imaging shows anterior disk displacement in the closed mouth position, however, as well as a return to a normal disk relationship during mouth opening in patients with clicking and popping; in patients with locking, the disk remains in the anterior position on attempted mouth opening, and movement of the condyle is limited. A small group of patients with locking show the intra-articular disk in normal position when the teeth are in occlusion, rather than anteriorly displaced, and no change in disk position occurs when the patient attempts to open the mouth.^{29,43} In such cases, adhesion of the disk to the articular eminence prevents translation of the condyle. These patients differ from those with anteriorly displaced, nonreducing disks in that they do not have a history of TMJ clicking preceding the sudden onset of locking.

Treatment

Initial treatment of patients with painful clicking or popping in the TMJ consists of a nonsteroidal anti-inflammatory drug; a soft, nonchewy diet; and use of a bite-opening appliance to reduce compression of retrodiskal tissue

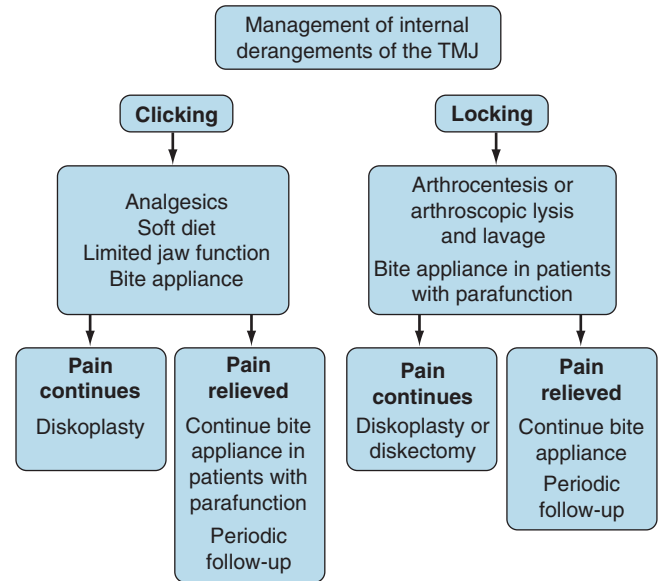

Figure 51-3 Management of internal derangements of the temporomandibular joint (TMJ). Patients with painful clicking or locking are treated medically initially, whereas patients with locking require surgical intervention.

(Figure 51-3). A muscle relaxant drug can be added to the regimen if the patient has associated myofascial pain. When the pain has stopped, no further treatment is necessary, although joint noise still may be present. A long-term follow-up study (1 to 15 years) of 190 patients with a history of clicking treated by such conservative nonsurgical modalities, which are not directed specifically to the problems of joint noise or disk displacement, showed that the condition worsened in only 1%, indicating that it is permissible to observe individuals with painless clicking as long as they remain otherwise asymptomatic.^{30,44} However, in those patients who have teeth-clenching and -grinding habits, use of a bite appliance is indicated to control these habits.

In patients with pain and clicking in the TMJ that is unresponsive to nonsurgical management, the disk should be repositioned arthroscopically or by open surgery (diskoplasty). Patients with parafunctional habits should continue the use of a bite appliance when sleeping. In patients with locking (anterior disk displacement without reduction), whether painful or not, treatment is urgent because if the condition is left untreated for a long time, subsequent management can be complicated by further degenerative changes in the disk and condyle that make disk salvage (diskoplasty) impossible. Initial treatment involves joint lavage and lysis of adhesions arthroscopically or by arthrocentesis. The latter involves establishment of inlet and outlet portals in the upper joint space with hypodermic needles, irrigation with lactated Ringer's solution to remove inflammatory tissue breakdown products and cytokines, and lysis of adhesions by hydraulic distention and manual manipulation of the joint (Figure 51-4).^{31,45}

The results of arthrocentesis parallel those achieved with arthroscopic lysis and lavage, and the procedure is less invasive. Although neither of these procedures restores the disk to its normal position, they do restore disk and joint mobility, and they reduce pain and improve function in most

Figure 51-4 Temporomandibular joint arthrocentesis. **A**, Hypodermic needles inserted into the upper joint space to allow lavage of the joint. **B**, Joint being irrigated with lactated Ringer's solution.

patients.^{32,33,46,47} In these patients, retrodiskal tissue within the joint undergoes fibrosis and acts as a pseudodisk. It is important that patients who have teeth-grinding or teeth-clenching habits are prescribed a bite appliance postoperatively to wear while sleeping.

In patients who do not respond favorably to arthroscopy or arthrocentesis, the displaced disk should be repositioned by an open operation. If the disk is extremely deformed and cannot be repositioned, or if a large, nonreparable perforation in the disk or a tear in the retrodiskal tissue is present, the disk should be removed. Although autogenous auricular cartilage or dermal grafts, or temporalis muscle flaps, have been used as a disk replacement, results have been unpredictable.^{31,45,48} More recent long-term studies have shown that most patients can tolerate a diskless joint.^{34,49} Currently, no acceptable alloplastic substitutes for the disk are available.

NEOPLASMS

Although primary neoplasms involving the TMJ are uncommon, they must be considered in the differential diagnosis of painful conditions affecting this region.^{35,36,50,51} Chondroma, osteochondroma, and osteoma are the most frequently encountered benign tumors, but isolated cases of fibro-osteoma, myxoma, fibrous dysplasia, giant cell reparative granuloma, aneurysmal bone cyst, synovium, synovial chondromatosis, chondroblastoma, osteoblastoma, glomus

tumor, and synovial hemangioma have been reported. Malignant tumors of the TMJ are even rarer, with infrequent reports of fibrosarcoma, chondrosarcoma, synovial fibrosarcoma, osteosarcoma, malignant fibrous histiocytoma, malignant schwannoma, leiomyosarcoma, and multiple myeloma. The TMJ also can be invaded by neoplasms from the cheek, the parotid gland, the external auditory canal, and the adjacent ramus of the mandible. Metastasis to the condyle from distant neoplasms in the breast, lung, prostate, colon, thyroid gland, liver, stomach, and kidney has been described.

Tumors of the TMJ can cause pain, limitation of jaw movement, deviation of the mandible to the affected side on attempted mouth opening, and difficulty in occluding the teeth. Depending on the nature of the condition, radiographs may show bony deformation, apposition, or resorption. A biopsy is necessary to establish the definitive diagnosis.

MYOFASCIAL PAIN AND DYSFUNCTION

Myofascial pain and dysfunction (MPD), or masticatory myalgia, is considered to be a psychophysiologic disease that primarily involves the muscles of mastication, and not the TMJ. Women are affected more frequently than men; the ratio in various reports ranges from 3:1 to 5:1. Although the condition can occur in children, the incidence seems to be greatest in adults 20 to 40 years old. MPD frequently is confused with painful conditions affecting the TMJ, such as degenerative arthritis or internal derangements, because patients with primary MPD can develop these diseases secondarily, and patients with primary joint disease can develop secondary MPD. Enhanced understanding of the causes and pathogenesis of this condition makes its diagnosis easier and its treatment more effective.^{37,38,52,53}

Etiology

Psychological stress has been suggested as an important contributing factor in the development of MPD (psychophysiologic theory).^{39,54,55} It is hypothesized that in most patients, stress-related, centrally induced increases in muscle activity, frequently combined with the presence of parafunctional habits such as clenching or grinding of the teeth, may result in associated muscle fatigue, pain, and limited mouth opening.^{40,54} However, similar symptoms occasionally have been seen to result from muscle overextension, muscle overcontraction, or trauma (Figure 51-5). A counter-theory (the pain adaptation theory of Lund)⁵⁶ has been proposed to suggest that pain in the masticatory muscles leads to a reduction rather than an increase in muscle activity as a protective mechanism, and this causes the limitation in mouth opening; however, this theory does not explain the origin of the pain. Despite extensive research, the cause of myofascial pain and dysfunction remains unknown.

Clinical Findings

Pain of unilateral origin is the most common symptom of MPD. In contrast to the pain associated with joint disease, which is well localized, the pain of muscle origin is more

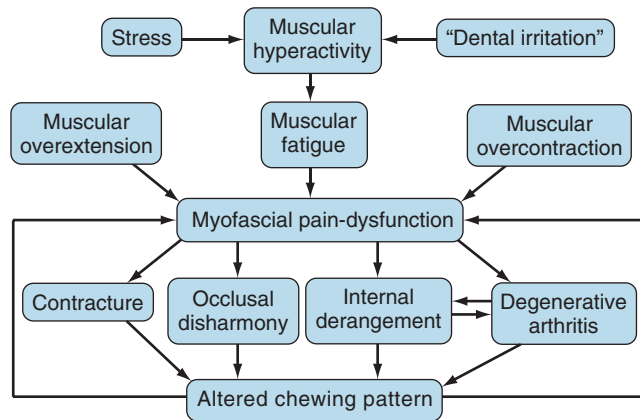

Figure 51-5 Causes of myofascial pain and dysfunction. Although the diagram shows three pathways, the one involving psychological stress is most common. The mechanism by which stress leads to myofascial pain and dysfunction is termed the *psychophysilogic theory*. (Modified from Laskin DM: *Etiology of the pain-dysfunction syndrome*, J Am Dent Assoc 79:147–153, 1969. Copyright © 1969 American Dental Association. Reprinted by permission of ADA Publishing Co., Inc.)

diffuse. The patient generally is unable to identify accurately the specific site involved; this can serve as an important diagnostic criterion in distinguishing between muscle and joint disorders.

Depending on the muscle involved, the pain associated with MPD may be described by the patient in various ways. The masseter is the muscle most frequently involved, and the patient usually refers to the pain as a jaw ache. The temporalis is the next most commonly involved muscle; it produces pain on the side of the head, which is interpreted by the patient as a headache. Involvement of the lateral pterygoid muscle produces earache or a deep pain behind the eye, whereas medial pterygoid involvement causes discomfort on swallowing and the feeling of a painful, swollen gland beneath the angle of the mandible. Medial pterygoid involvement also can cause stiffness or a full feeling in the ear.

The pain associated with MPD is usually constant, but it is often more severe on arising in the morning or may worsen gradually as the day progresses. Pain generally is exacerbated by jaw function, especially during such activities as eating and excessive talking. Myofascial pain tends to be regional rather than local, and patients with a long-standing problem may complain that pain in the facial region has spread to the cervical area and later to the shoulders and back.

Tenderness in the muscles of mastication, another common finding, can be used to confirm the source of the pain in muscles that are accessible to palpation (masseter, temporalis, and medial pterygoid). Although muscle tenderness usually is not reported by the patient, this symptom can be elicited easily by the examiner. The most frequent sites of tenderness are near the angle of the mandible, in the belly and the posterosuperior aspect of the masseter, in the anterior temporal region, and over the temporal crest on the anterior aspect of the coronoid process. The location of some of the tender areas suggests that tendons may be a source of pain and tenderness.

Limitation of mandibular movement is the third cardinal symptom of MPD. It manifests as an inability to open the mouth as wide as usual and as a deviation of the mandible

to the affected side when mouth opening is attempted. Lateral excursion to the unaffected side is reduced. The limitation of mandibular movement usually is correlated with the amount of pain present.

A clicking or popping sound in the TMJ is another finding in some patients with MPD. This is not a cardinal sign, however, because it occurs only in patients with a chronic teeth-clenching habit, which gradually produces frictional changes in the joint and subsequent disk displacement.^{26,40} The presence of joint sounds alone is insufficient to allow a diagnosis of MPD. Joint sounds must be accompanied by myofascial pain and tenderness in the masticatory muscles that began before the onset of the joint noise. Such patients must be distinguished from patients with a primary internal derangement, in whom muscle splinting produces myofascial pain and tenderness after the onset of the joint noise. The history and differences in physical findings are helpful in making this distinction.

In addition to having the three cardinal symptoms of pain, muscle tenderness, and limitation of mouth opening, patients with MPD usually have no clinical or radiographic evidence of pathologic changes in the TMJ. These negative characteristics are important in establishing the diagnosis because they confirm that the primary site of the problem is not the articular structures.

Diagnosis

Because the cardinal signs and symptoms of MPD are similar to those produced by such organic problems involving the TMJ as degenerative joint disease and internal disk derangement and by a variety of nonarticular conditions (see [Tables 51-1 and 51-2](#)), diagnosis of this condition can be difficult, requiring a careful history and a thorough clinical evaluation. Periapical radiographs of the teeth and screening radiographs (transcranial, transpharyngeal, or panoramic) of the TMJs can be helpful in eliminating dental problems or gross joint disease. If screening views of the TMJs show some abnormality, CT scans are usually advisable for confirmation. MRI also can be useful in determining the position of the disk when an internal derangement of the TMJ is being considered. Depending on the suspected condition, other radiographic views of the head and neck and scintigraphy may be needed to establish a final diagnosis.

Certain laboratory tests may be helpful in some instances. These include a complete blood cell count if an infection is suspected; serum calcium, phosphorus, and alkaline phosphatase measurements for possible bone disease; serum uric acid determination for gout; serum creatinine and creatine kinase levels as indicators of muscle disease; and erythrocyte sedimentation rate, rheumatoid factor, latex fixation, and antinuclear antibody tests for suspected rheumatoid arthritis. Electromyography can be used to evaluate muscle function. Psychological evaluation and psychometric testing are good research tools, but they have little diagnostic value other than in identifying the presence of associated abnormal behavioral characteristics.

A condition that sometimes is confused with myofascial pain is fibromyalgia, particularly when MPD involves several regions in addition to the face. Although a small subset of patients with MPD eventually may develop fibromyalgia, these are probably distinct conditions.^{41,57} [Table 51-4](#) lists

Table 51-4 Distinguishing Features of Myofascial Pain and Fibromyalgia

	Myofascial Pain	Fibromyalgia
Age distribution	20-40 years	20-50 years
Gender distribution	Mainly women	Mainly women
Distribution of pain	Localized; usually unilateral	Generalized; bilaterally symmetric
Tender points	Few	Multiple
Trigger points	Uncommon	Common
Fatigue	Localized muscle fatigue	Generalized fatigue
Sleep disturbance	Common	Common

the distinguishing characteristics of myofascial pain versus fibromyalgia.

Treatment

Treatment of MPD is divided into four phases.^{42,58} When a definitive diagnosis is made, phase I therapy should be started (Figure 51-6). Phase I therapy initially involves providing the patient with some understanding of the problem. Because patients often have difficulty accepting a psychophysiologic explanation for their condition, the discussion should deal with the issue of muscle fatigue as the cause of the pain and dysfunction, delaying consideration of the role of stress and psychological factors until the symptoms have improved, and the patient's confidence has been gained. Relating the symptoms to the specific masticatory muscles from which they arise helps the patient understand the reason for the type and location of the pain—headache from the temporalis muscle, jaw ache from the masseter muscle, discomfort on swallowing and stuffiness in the ear from the medial pterygoid muscle, and earache and pain behind the eye from the lateral pterygoid muscle.

In addition to the initial explanation, the patient should be counseled regarding home therapy; this includes recommendations about avoidance of clenching and grinding of the teeth, eating a soft diet, use of moist heat and massage on the masticatory muscles, and limitation of jaw movement. A nonsteroidal anti-inflammatory drug should be prescribed for the pain. In patients who have problems sleeping, a small dose of amitriptyline at bedtime is helpful in improving sleep and reducing parafunction.

About 50% of these patients experience resolution of their symptoms within 2 to 4 weeks with phase I therapy. For patients whose symptoms persist, phase II therapy is initiated. Home therapy and medications are continued, and a bite appliance is made for the patient. Although numerous types have been used, the Hawley-type maxillary appliance is probably most effective because it prevents contact of the posterior teeth and prevents most forms of parafunctional activity (Figure 51-7).^{43,59} The appliance generally is worn at night, but it can be worn for 5 to 6 hours during the day, if necessary. The appliance should not be worn continuously, however, because the posterior teeth may supraerupt in some patients.

With phase II therapy, another 20% to 25% of patients become symptom free in 2 to 4 weeks. When the patient

becomes symptom free, the medications are stopped first, and wearing the bite appliance is discontinued next. If the patient has a return of symptoms, and the appliance is worn only at night, its use can be continued indefinitely.

Patients who do not respond to the use of a bite appliance are entered into phase III treatment for 4 to 6 weeks. In this phase, physical therapy (heat, massage, ultrasound, electrogalvanic stimulation)⁶⁰ or relaxation therapy (electromyographic biofeedback, conditioned relaxation)⁶¹ is added to the regimen. No evidence shows that one form of treatment is better than another, and either can be used

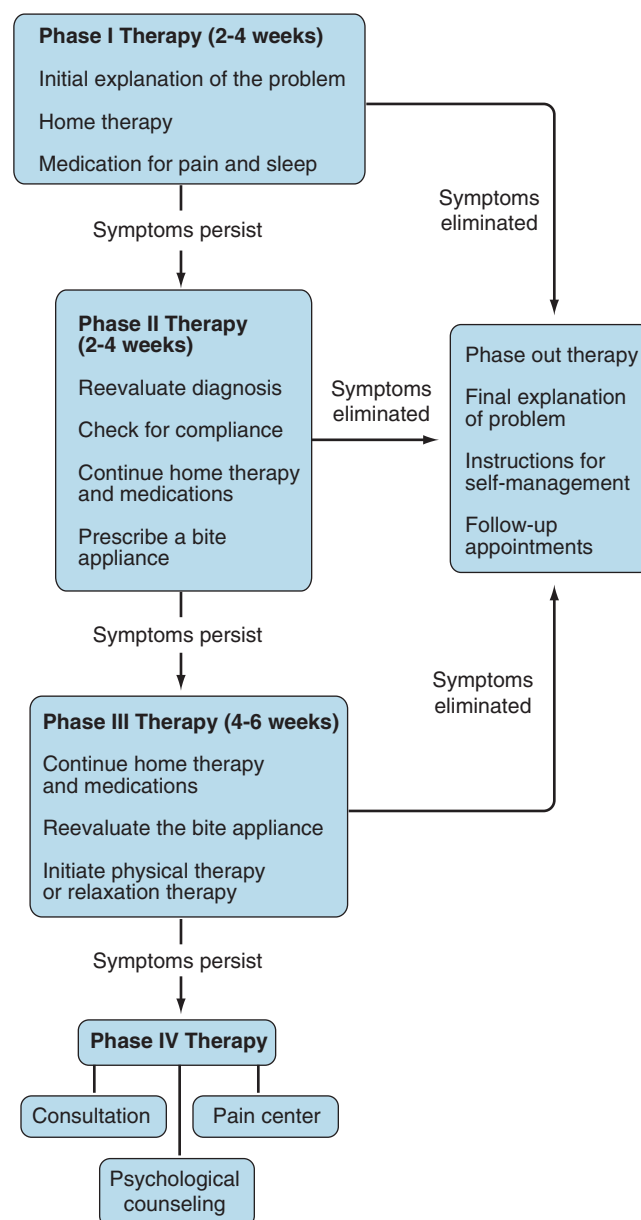

Figure 51-6 Management of myofascial pain and dysfunction. Treatments are divided into four phases. If the symptoms are eliminated in any of the first three phases, the ongoing therapy is gradually phased out, and the patient is instructed in continued self-management of the condition. (Modified from Laskin DM, Block S: *Diagnosis and treatment of myofascial pain dysfunction [MPD] syndrome*, J Prosthet Dent 56:75-84, 1986.)

Figure 51-7 Hawley-type maxillary bite appliance. Only the anterior teeth contact the appliance, and space between the posterior teeth is evident (arrow).

first. If one is unsuccessful, the other can be tried. Phase III therapy usually helps another 10% to 15% of patients.

If all of these approaches fail, and no question arises about the correctness of the diagnosis, psychological counseling is recommended. This counseling involves helping patients identify possible stresses in their lives and learning to cope with such situations. If the diagnosis is in doubt, the patient should be referred first for appropriate dental and neurologic consultation and re-evaluation. Another alternative is to refer patients with recalcitrant MPD to a TMJ center or pain clinic because such patients generally require a multidisciplinary approach for successful treatment.

SUMMARY

Successful management of patients with temporomandibular disorders depends on establishing an accurate diagnosis and using proper therapy based on an understanding of the cause of the condition being treated. Of particular importance is separating patients with MPD, who constitute the major group encountered and who are not surgical candidates, from patients with TMJ disease, who frequently require surgical treatment. Even in the latter group, many commonly encountered conditions, such as arthritis and internal disk derangements, often respond to nonsurgical therapy, and this type of treatment should be given a fair trial before more aggressive management is considered.

KEY POINTS

Many issues that surround fibromyalgia are not scientific ones—it is widely agreed that pain and suffering are real; instead, the primary issues are often social, political, and financial.

Fibromyalgia lies at the end of a continuum of polysymptomatic distress rather than being a discrete disorder.

Fibromyalgia may be diagnosed with American College of Rheumatology (ACR) 2010 or 1990 criteria, but clinical care does not require a diagnosis.

The ACR 2010 criteria should result in changes in the sex ratio of patients with fibromyalgia because men have higher pain thresholds and are therefore less likely to be diagnosed as having fibromyalgia than women when the 1990 criteria including tender points are used.

Advanced neuroimaging techniques showed dysfunctioning of hippocampus and other cerebral abnormalities in fibromyalgia patients, as well as greater gray matter loss than in healthy controls.

The regions in which objective changes are demonstrated may be functionally linked to core features of the disorder including affective disturbances and chronic widespread pain.

Advanced neuroimaging techniques indicate that central factors are important in the processing of pain in people with fibromyalgia and suggest that they have a narrow range of tolerance for pain and perhaps other sensory stimuli before it becomes noxious.

Pharmacologic treatment is of limited value, but caring, comprehensive care can make a difference.

Fibromyalgia is a controversial disorder.¹ Certain aspects of the controversies surrounding fibromyalgia reflect scientific disagreements about categorization, pathophysiology, and treatment (Figure 52-1). But another important reason for controversy is that the diagnosis carries with it profound societal consequences. Whether fibromyalgia “exists” or is “real” or should be valued matters a great deal to patients, payers, pension systems, researchers, professional and patient organizations, and pharmaceutical companies.²

Fibromyalgia is a clinical syndrome that is defined by the presence of generalized pain, fatigue, unrefreshed sleep, multiple somatic symptoms, cognitive problems, and other symptoms, often including depression. Symptoms important to the fibromyalgia case definition are shown in Figure 52-2 in order of their importance.³ The 2010 American College of Rheumatology (ACR) preliminary diagnostic criteria for fibromyalgia require the presence of widespread pain and

Fibromyalgia

FREDERICK WOLFE • JOHANNES J. RASKER

multiple symptoms (Table 52-1).³ The more restrictive ACR 1990 classification criteria require the presence of widespread pain plus the presence of tenderness on palpation in at least 11 of 18 specified “tender point” sites.⁴ Fibromyalgia can be diagnosed in the presence of other medical conditions and is never a diagnosis of exclusion. However, concomitant disorders associated with musculoskeletal pain and fatigue will always need to be identified.

THE FIBROMYALGIA CONSTRUCT

One Syndrome or One of Many?

The central features of fibromyalgia that were noted earlier are also found in illnesses such as chronic fatigue syndrome, irritable bowel syndrome, headache syndromes, and multiple chemical sensitivities, among many others (see Figure 52-1).⁵ Taken together, these syndromes have been called functional somatic syndromes (FSS).⁶ Because the symptom content of the syndromes is similar, as are the treatments and the demographic characteristics of patients who have the disorders, it has been suggested by many that a single diagnostic term, rather than individual syndrome names, should be used for diagnosis. These suggestions derive mostly from the psychiatric literature.⁷⁻⁹ Terms suggested include FSS and bodily pain disorder.⁹ However, if fibromyalgia is just a name given to the disorder primarily by rheumatologists, but does not differ essentially from other somatic syndromes, then fibromyalgia does not exist as a separate syndrome. Fibromyalgia versus FSS creates a series of problems. FSS connotes a strong psychologic component, which is undesirable to patients, pharmaceutical companies, and medical researchers. In addition, there is the logical inconsistency in which regulatory authorities such as the U.S. Food and Drug Administration (FDA) approve treatments for the select fibromyalgia indication, when fibromyalgia is not different from other FSS. The FDA mandate strengthens the position of fibromyalgia as a “separate” disease, although there is little evidence that it is such an entity.^{7,10}

A Separate Syndrome or Part of a Continuum?

Fibromyalgia is properly considered to lie “at the extreme end of the spectrum of polysymptomatic distress.”¹¹ Fibromyalgia diagnosis depends on splitting the distress continuum, placing on one side of the divide those with fibromyalgia and on the other side all other persons. Polysymptomatic distress refers to problems in many symptom areas—pain, fatigue, sleep disturbance, functional impairment, psychologic status, and so on. Because symptoms are correlated, persons with high levels of one symptom will

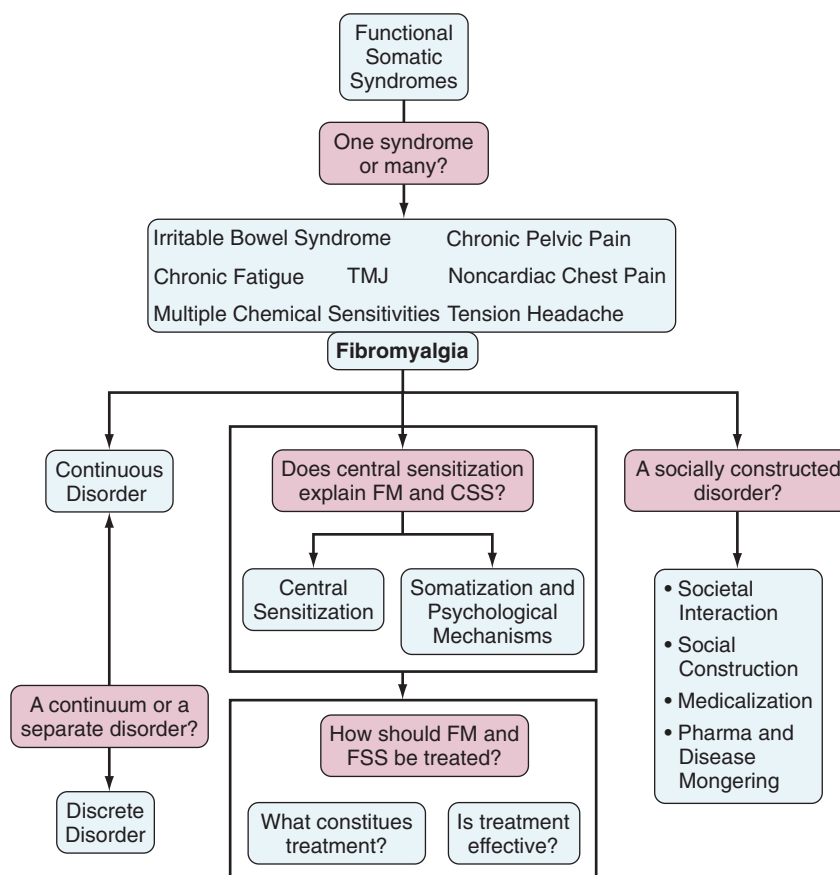

Figure 52-1 Fibromyalgia controversies. CSS, central sensitivity syndrome; FM, fibromyalgia; FSS, functional somatic syndromes; TMJ, temporomandibular joint.

Figure 52-2 Symptoms that differentiate patients who satisfy American College of Rheumatology 1990 criteria from other rheumatic disease patients with noninflammatory rheumatic pain disorders sorted by strength of association.³ The two figures represent different measures of association. Higher scores mean stronger associations. (C), categorical variable; IBS, irritable bowel syndrome; WPI, Widespread Pain Index.

Table 52-1 American College of Rheumatology 2010 Preliminary Diagnostic Criteria for Fibromyalgia³

Criteria				
A patient satisfies diagnostic criteria for fibromyalgia if the following 3 conditions are met:				
1. Widespread Pain Index (WPI) ≥ 7 and Symptom Severity Score ≥ 5 or WPI between 3 and 6 and Symptom Severity Score ≥ 9 .				
2. Symptoms have been present at a similar level for at least 3 months.				
3. The patient does not have a disorder that would otherwise explain the pain.				
Ascertainment				
1. WPI: Note the number areas in which the patient has had pain over the past week. In how many areas has the patient had pain? Score will be between 0 and 19.				
Shoulder girdle, Lt.	Hip (buttock, trochanter), Lt.	Jaw, Lt.	Upper back	
Shoulder girdle, Rt.	Hip (buttock, trochanter), Rt.	Jaw, Rt.	Lower back	
Upper arm, Lt.	Upper leg, Lt.	Chest	Neck	
Upper arm, Rt.	Upper leg, Rt.	Abdomen		
Lower arm, Lt.	Lower leg, Lt.			
Lower arm, Rt.	Lower leg, Rt.			
2. Symptom Severity Score:				
Fatigue				
Waking unrefreshed				
Cognitive symptoms				
For the each of the three symptoms above, indicate the level of severity over the past week using the following scale:				
0 = No problem				
1 = Slight or mild problems; generally mild or intermittent				
2 = Moderate; considerable problems; often present and/or at a moderate level				
3 = Severe: pervasive, continuous, life-disturbing problems				
Considering somatic symptoms* in general, indicate whether the patient has:				
0 = No symptoms				
1 = Few symptoms				
2 = A moderate number				
3 = A great deal of symptoms				
The Symptom Severity Score is the sum of the severity of the three symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general. The final score is between 0 and 12.				

*For reference purposes, here is a list of somatic symptoms that might be considered: muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

tend to have high levels of other symptoms. As an aggregate concept, polysymptomatic distress cannot be measured directly but can be approximated with the use of surrogate variables. One such surrogate measure of polysymptomatic distress is the fibromyalgia symptom scale—also called the fibromyalgiance scale.¹² This scale represents the summation of the Widespread Pain Index (the number of body sites reported as painful) and characteristic fibromyalgia symptoms used in the ACR 2010 preliminary diagnostic criteria.³ In patients with various rheumatic diseases followed in the U.S. National Data Bank for Rheumatic Diseases,¹³ the upper part of Figure 52-3 shows the relation between the scale and the Short Form-36 (SF-36) Physical Component Summary (PCS) score, the EQ5D Quality of Life score, and the patient's estimate of global severity. A value of 13 on the fibromyalgiance scale best divides fibromyalgia-positive and fibromyalgia-negative patients.¹⁴ It can also be seen that the Widespread Pain Index alone is similarly associated with these three measures of illness severity (see Figure 52-3, lower part). About 2% to 4% of the adult population meets criteria for fibromyalgia. One can sense in the figure the distribution of polysymptomatic distress and its correlation with quality of life. Note that polysymptomatic distress is a quantity that exists in all persons, not just in those with fibromyalgia, though it is greater in those with fibromyalgia.

The higher the score on the polysymptomatic distress scale and the Widespread Pain Index, the more likely we are to find evidence of social disadvantage such as lower income, less education, and childhood mistreatment, and we will also find more psychologic distress and abnormality; it appears that these factors play a role in the development of fibromyalgia-like symptoms and symptom intensification.¹⁴ Fibromyalgiance differs from other measures of polysymptomatic distress by the centrality of musculoskeletal pain because nonarticular musculoskeletal pain is a central component of the scale.

To define fibromyalgia by criteria, we must, in effect, draw a line on the distress continuum and say that those beyond this line have fibromyalgia and those before it do not. In the ACR 2010 criteria (see Table 52-1),³ the cut point is identified by the extent of widespread pain and fibromyalgia symptoms. In the 1990 criteria (Table 52-2), the cut point is represented by a combination of tender points and widespread pain. Both cut points, though aided by data analyses, are determined by committees. There is nothing intrinsic in the polysymptomatic distress scale that tells us where the dividing point is. But in the general population a PCS score of 50 represents the population mean, with each standard deviation representing 10 units. At a fibromyalgiance score of 13, patients designated as

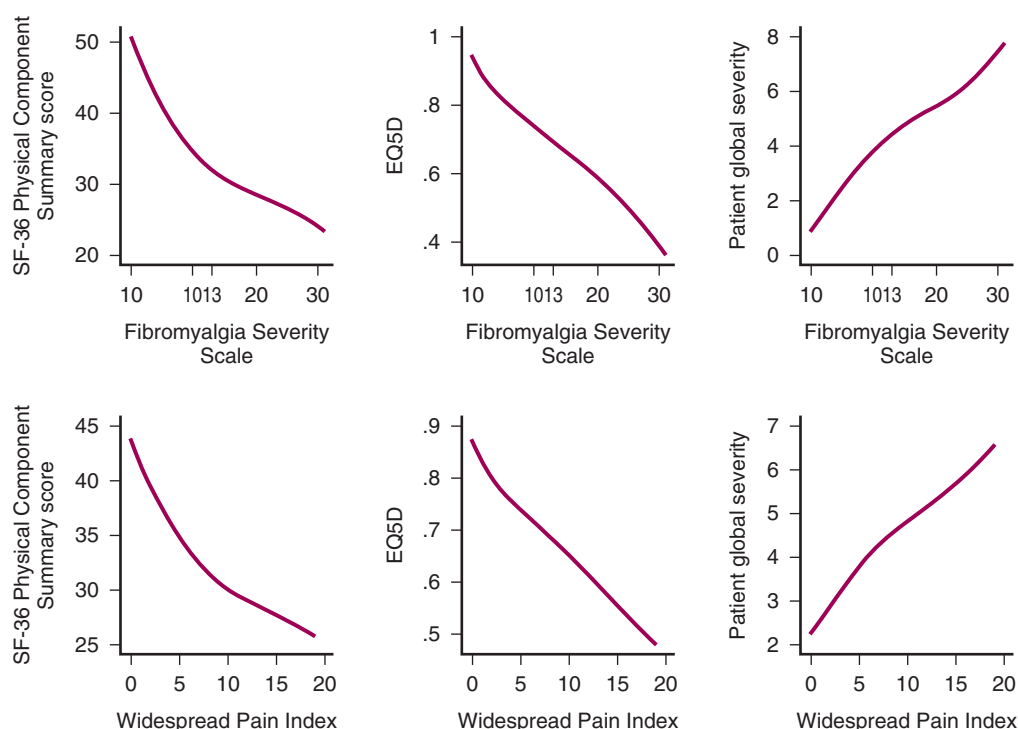

Figure 52-3 Assessment of polysymptomatic distress. A value of 13 on the Fibromyalgia Severity Scale is the best dividing point between fibromyalgia criteria-positive and fibromyalgia criteria-negative patients. EQ5D, EuroQoL; SF-36, Short Form-36.

fibromyalgia have a PCS score about 2 standard deviations below the mean (see Figure 52-3, upper left). Thus fibromyalgia diagnosis identifies persons with substantially reduced quality of life—those at the “extreme end of the spectrum of polysymptomatic distress.”¹¹

Social Construction and Medicalization

Many physicians doubt the existence of fibromyalgia as a separate entity, considering instead that it is a primarily a psychologic illness—not a “real disease”^{11,15-17} (see Figures

52-1 and 52-4). Epidemiologic and clinical studies give no support to the idea that fibromyalgia is a distinct entity¹⁸⁻²⁰; instead, they support the contrary idea that fibromyalgia represents the end of a spectrum of polysymptomatic distress.

Illnesses exist within societies, and their existence and phenotype are often a function of the degree of acceptance of the disorder.²¹ The idea and consequences of fibromyalgia as a socially constructed, medicalized disorder has been discussed at length.² An illness may be considered to be socially constructed when it is at least in large part the consequence

Table 52-2 1990 American College of Rheumatology Criteria for the Classification of Fibromyalgia*

1. History of Widespread Pain
<i>Definition:</i> Pain is considered widespread when all of the following are present: pain in the left side of the body, pain in the right side of the body, pain above the waist, and pain below the waist. In addition, axial skeletal pain (cervical spine or anterior chest or thoracic spine or low back) must be present. In this definition, shoulder and buttock pain is considered as pain for each involved side. “Low back” pain is considered lower segment pain.
2. Pain in 11 of 18 Tender Point Sites on Digital Palpation
<i>Definition:</i> Pain, on digital palpation, must be present in at least 11 of the following 18 sites: Occiput: bilateral, at the suboccipital muscle insertions. Low cervical: bilateral, at the anterior aspects of the intertransverse spaces at C5-C7. Trapezius: bilateral, at the midpoint of the upper border. Supraspinatus: bilateral, at origins, above the scapula spine near the medial border. Second rib: bilateral, at the second costochondral junctions, just lateral to the junctions on upper surfaces. Lateral epicondyle: bilateral, 2 cm distal to the epicondyles. Gluteal: bilateral, in upper outer quadrants of buttocks in anterior fold of muscle. Greater trochanter: bilateral, posterior to the trochanteric prominence. Knee: bilateral, at the medial fat pad proximal to the joint line. Digital palpation should be performed with an approximate force of 4 kg. For a tender point to be considered “positive,” the subject must state that the palpation was painful. “Tender” is not to be considered “painful.”

*For classification purposes, patients will be said to have fibromyalgia if both criteria are satisfied. Widespread pain must have been present for at least 3 months. The presence of a second clinical disorder does not exclude the diagnosis of fibromyalgia.

From Wolfe F, Smythe HA, Yunus MB, et al: The American College of Rheumatology 1990 Criteria for the Classification of Fibromyalgia. Report of the Multicenter Criteria Committee, *Arthritis Rheum* 33(2):160–172, 1990.

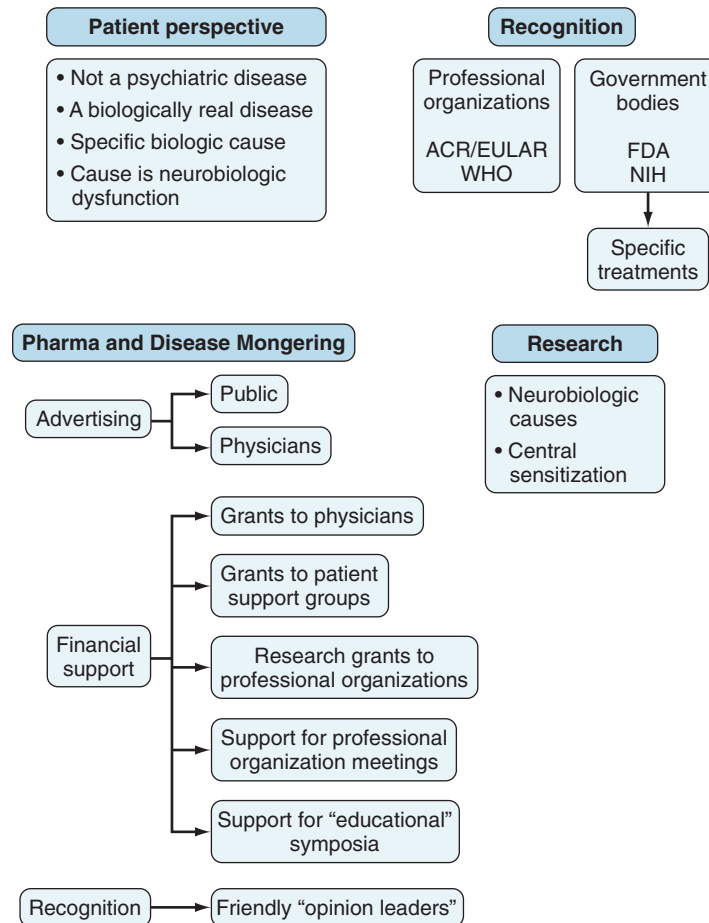

Figure 52-4 Nonmedical and societal issues and concerns in fibromyalgia. ACR/EULAR, American College of Rheumatology/European League Against Rheumatism; FDA, U.S. Food and Drug Administration; NIH, National Institutes of Health; WHO, World Health Organization.

of societal factors²² that result in “the creation (or construction) of new medical categories with the subsequent expansion of medical jurisdiction.”²³ Medicalization is “a process in which nonmedical problems become defined and treated as medical problems, usually in terms of illness and disorders [and are] described using medical language, understood through the adoption of a medical framework, or treated with a medical intervention.”²⁴

Ivan Illich’s 1976 description of medicalization in society set out some markers that are germane to understanding fibromyalgia and opposition to it.²⁵ Illich wrote: “In a morbid society the belief prevails that defined and diagnosed ill-health is infinitely preferable to any other form of negative label or to no label at all” and that “people want to hear the lie that physical illness relieves them of social and political responsibilities.” He called these people “innocent victim[s] of biological mechanisms. . . .” In addition, he said diagnosed “ill-health” provides access to disability programs and access to additional health care.²⁵ Data from research about the neurobiologic investigations of pain mechanisms are offered as strong support that persons with fibromyalgia are “innocent victim[s] of biological mechanisms . . .”²⁶

Given the social construction of fibromyalgia, medicalization is driven primarily by three components (see Figure 52-4). The first is the primary need for patients with fibromyalgia and other FSS for legitimization: Others need to understand that the problem is real and serious, and not

primarily a psychosomatic illness.² The diagnosis of a “valid” fibromyalgia provides entry to medical insurance and treatment and is grounds for work disability and pension. Extensive networks of patient organizations throughout the world work toward this purpose.² The second pillar of medicalization in fibromyalgia is the pharmaceutical industry.²⁷ Direct-to-patient advertising is ubiquitous. Often deceptive, it seeks to expand the definition of fibromyalgia, entice persons with pain and fatigue into the diagnosis, and strongly promote its treatments as effective.²⁷ Industry financially supports patient and professional organization, medical education and symposia,^{2,28} and advertising in professional and lay journals. Virtually all major authors of fibromyalgia studies have received pharmaceutical company support. The influence of drug companies has increased dramatically in the past two decades to the extent that “ . . . companies are having an increasing impact on the boundaries of the normal and the pathological, becoming active agents of social control.”²³

Although “medicalization is now more driven by commercial and market interests than by professional claimsmakers,”²³ physicians and professional organizations remain the important sources of scientific support, and National Institutes of Health grants for fibromyalgia research have become common.

The more fibromyalgia is seen as a “real disease” with strong criteria, reliable assessments and professional support,

the more the claims of patients will be taken seriously, the more drugs will be sold and consumed, and the more financial and intellectual support will come to researchers and professional organizations. By contrast, perceiving fibromyalgia as an FSS and part of a continuum with assessments that are not always reliable weakens support for the syndrome and those who have it. The issues that surround fibromyalgia are not scientific ones—it is widely agreed that pain and suffering are real; instead, the issues are social, political, and financial.

Historical Development

Attempts to characterize and diagnose fibromyalgia have gone through several changes in conceptualization. The earliest roots of the syndrome can be found in the nineteenth century perception of abnormal connective tissue and muscles. In various forms, this concept held sway until the late 1970s when a new emphasis on sleep disturbance and tender points led to proposed clinical criteria that included sleep disturbance and tenderness to palpation at 12 of 14 selected sites.²⁹ In the early 1980s, most of the other fibromyalgia-associated symptoms were identified, and unofficial criteria were proposed that combined symptoms with tenderness.³⁰ With the publication of the ACR criteria in 1990,⁴ the fibromyalgia case definition was reduced to generalized pain and the presence of multiple tender points. The 1990 criteria, supported by the imprimatur of the ACR, gave the syndrome official sanction. With the criteria publication, professional opposition to fibromyalgia solidified and has continued until the present.^{2,31-37} In 2010 the ACR preliminary diagnostic criteria³ were published. These criteria expanded the case definition and criteria items to include widespread pain and multiple symptoms including fatigue, disturbed sleep, cognitive symptoms, and multiple somatic symptoms. Despite scientific data questioning the validity of fibromyalgia as a distinct entity, fibromyalgia has become a dominant paradigm, supported strongly by funding and influence of the pharmaceutical industry. At present there are currently several opposing views of fibromyalgia. One view holds that it is not distinct and is a part of FSS,^{7,9,10} with a functional symptom being defined as one that “after appropriate medical assessment, cannot be explained in terms of a conventionally defined medical disease.”⁷ The second view, and the dominant paradigm, supports the concept that fibromyalgia is a disorder of “... aberrant central pain transmission... [in which] purely behavioral or psychologic factors are not primarily responsible for the pain and tenderness...”³⁸ A third view holds that fibromyalgia is the end of a spectrum of polysymptomatic distress and is not a distinct entity.^{2,11} Perhaps, not surprisingly, these views are not mutually exclusive.

CLINICAL FEATURES

Fibromyalgia is characterized by high levels of pain, sleep disturbance, and fatigue combined with a general increase in medical symptoms (Table 52-3) including problems of memory or thinking and often psychologic distress.³⁹

Individuals with the syndrome are unusually sensitive to digital pressure (tender points) in certain body areas. Clinically, fibromyalgia is often identified or suspected by the

Table 52-3 Prevalence of Specific Symptoms among 2784 Patients with Fibromyalgia in the National Data Bank for Rheumatic Diseases

Symptom	%
Sleep problems	89.1
Fatigue or tiredness	88.6
Muscle pain	85.2
Muscle weakness	70.2
Paresthesias	67.6
Cognitive problems	66.3
Headache	64.7
Dry mouth	53.3
Insomnia	51.8
Easy bruising	49.1
Dry eyes	47.5
Depression	47.5
Blurred vision	47.0
Irritable bowel syndrome	46.3
Heartburn	44.4
Itching	44.3
Dizziness	42.1
Constipation	41.9

Vomiting	9.1
Seizures	1.7

inexplicability and severity of symptoms and by their number. The most common defining symptom is that of generalized pain (“pain all over”), and pain all over, or widespread pain, is a requirement of the 1990 and 2010 criteria. The clinician may be surprised by the extent and severity of symptoms (see Table 52-3 and Figure 52-3) and surprised at unexpected emotional distress. Fibromyalgia has a quality of inexplicability and unexpectedness.

Upper and lower back pain is the most common pain problem (>80%). Many patients, at the clinical interview, emphasize only a few areas of pain. Questions specifically directed to other areas may elicit reports of pain that were not stated spontaneously. Patients with fibromyalgia may complain of greater pain in an osteoarthritic joint than patients without fibromyalgia. Although musculoskeletal pain is central to fibromyalgia, patients may be more concerned about fatigue or memory problems.

Fibromyalgia patients perform more poorly in formal cognitive testing than age-matched controls.⁴⁰ In the National Data Bank for Rheumatic Diseases in 2006, 66% of 2784 fibromyalgia patients complained of memory or thinking problems compared with 31% of 24,479 patients with other rheumatic conditions. The most common symptoms, found

in more than two-thirds of patients, are sleep problems, fatigue, muscle pain, paresthesias, and cognitive problems (see Table 52-3). In addition, the prevalence of other important symptoms is as follows: headache, 65%; depression, 48%; and irritable bowel syndrome, 46% (see Table 52-3). A high count of symptoms is characteristic of fibromyalgia and is frequently a key item in the 2010 diagnostic criteria to diagnosis (see Figure 52-2). Fibromyalgia is also associated with increased reporting of comorbid conditions.^{41,42} The typical picture of fibromyalgia emphasizes certain symptoms (pain, fatigue, sleep disturbance, cognitive problems) and an abundance of symptoms and comorbidities. Given the high levels of symptom variables and membership at the tail of the pain-distress continuum, it is not surprising that evidence of psychosocial disruption and high rates of lifetime psychiatric illness are found.^{43,44}

Fibromyalgia occurs frequently in other rheumatic disorders including rheumatoid arthritis, osteoarthritis, and systemic lupus erythematosus, in which the prevalence of fibromyalgia exceeds 20%. The clues to identifying fibromyalgia in the presence of other painful disorders are location of pain (nonarticular), continued pain and distress despite objective improvement in the concomitant disorder, and unusual fatigue.

ASSESSMENT AND DIAGNOSIS OF A PATIENT WITH FIBROMYALGIA

Diagnosis and Diagnostic Criteria

A number of approaches to fibromyalgia diagnosis are available. To treat patients, recognition of the degree of pain, fatigue, and other symptoms is necessary, but a specific diagnostic term is not.^{2,11} Chronic pain syndrome, FSS, or fibromyalgia will all suffice for a diagnostic term in most settings. But in countries such as the United States, chronic pain syndrome or FSS often may not be sufficient for access to insurance reimbursement or pension systems. In addition, direct-to-patient advertising may influence diagnostic terminology and diagnosis toward fibromyalgia.

Today, two sets of valid criteria for fibromyalgia are used in most of the world, although country-specific criteria also exist.⁴⁵ The approach to fibromyalgia diagnosis should differ according to the setting and the physician's underlying beliefs about fibromyalgia acceptability. The 1990 ACR classification criteria (see Table 52-2)⁴ require the presence of widespread pain and the identification of pain on palpation at 11 or more of 18 tender points. Until 2010, with the publication of the ACR preliminary diagnostic criteria,³ the 1990 criteria was the only method for an official diagnosis. The 2010 diagnostic criteria are easier in some ways and more difficult in others. They are easier because they eliminate the tender point examination that may be difficult for some examiners. The 2010 criteria are more difficult because they require a thorough symptom evaluation. One advantage of the 2010 criteria is that the examiner/interviewer becomes much more familiar with the spectrum and degree of the patient's problem. But for the criteria to work correctly, the interviewer must be comprehensive and thorough. The 2010 criteria provide two scales to evaluate the degree of polysymptomatic distress: the symptom severity scale and the fibromyalgianess scale, both

of which are discussed earlier. The fibromyalgianess scale has the advantage that it is a continuous measure of polysymptomatic distress. It is suitable for use in all patients whether or not they satisfy fibromyalgia criteria now or have satisfied them in the past. The scale is also useful when the physician or examiner does not believe in the fibromyalgia concept because it does not require a criteria diagnosis to be useful. The ACR 2010 criteria have been modified by the authors so that self-report forms can be used.¹⁴ Although these self-report, form-based criteria can be useful for survey and clinical research, they have not been endorsed by the ACR and they should never be used for clinical diagnosis.

Primary, Secondary, and Secondary-Concomitant Fibromyalgia

Fibromyalgia is sometimes divided into primary, secondary, and secondary-concomitant fibromyalgia. The term *primary fibromyalgia* is most often used when there is not another condition with symptoms that could explain fibromyalgia symptoms. This division between primary and secondary fibromyalgia is artificial, however. Back pain in older individuals when age-related radiographic changes are present might be considered *secondary fibromyalgia*, whereas the same symptoms in younger individuals might be considered *primary fibromyalgia*. The ACR 1990 criteria study⁴ showed no difference between primary and secondary fibromyalgia with regard to symptoms and diagnosis. The usefulness of primary fibromyalgia occurs in clinical trials, in which it is desirable to ensure those symptoms are not coming from another well-established illness. A fibromyalgia diagnosis implies understanding of issues such as pain, fatigue, sleep, and cognitive and emotional problems. When fibromyalgia is considered only in patients without other musculoskeletal conditions, the "benefit" of fibromyalgia diagnosis—its consideration of symptom issues and extent of pain—is lost. If fibromyalgia is to be diagnosed or considered, such consideration should be applied to all patients. As noted earlier, fibromyalgia is never a diagnosis of exclusion. When fibromyalgia is diagnosed in the presence of another condition, treatment is indicated for one or both disorders, as determined clinically.

Differential Diagnosis

The primary symptoms of fibromyalgia, widespread pain and fatigue, can be found in many medical disorders. Similarly, fibromyalgia can coexist with other medical conditions. The proper approach to avoiding misdiagnosis is to ascertain the presence or absence of fibromyalgia and then to determine whether other disorders with widespread pain and fatigue are present. Practically, the categories are fibromyalgia AND other disorders, fibromyalgia AND NOT other disorders, and other disorders AND NOT fibromyalgia. Conditions with fibromyalgia-like features include polymyalgia rheumatica, polymyositis, lupus, cervical spine disorders, hypermobility syndromes, endocrine and paraneoplastic disorders, and forms of polyarthritis including rheumatoid arthritis and ankylosing spondylitis. When differential diagnosis is problematic, it is because the other medical condition is difficult to diagnose or has not been

evaluated properly. The clue to understanding a patient's illness is thoroughly evaluating the patient with a careful history, physical examination, and laboratory evaluation.

ASSESSMENT OF FIBROMYALGIA SEVERITY

Self-Report Measures

The ACR 2010 preliminary diagnostic criteria provided a new measure of fibromyalgia severity, the Symptom Severity Score (see Table 52-1).³ Used in the diagnosis of fibromyalgia, this scale also functions as a measure of the severity of fibromyalgia symptoms and can be useful independently of the criteria. Another scale that is an effective measure is the fibromyalgianess scale.^{14,46} It is the sum of the two items used in the 2010 criteria, the Widespread Pain Index and the Symptom Severity Score. It is suitable for use in all patients, regardless of fibromyalgia status, thereby integrating fibromyalgianess and fibromyalgia symptoms into general patient care.

Symptom severity, physical function, and work status are the key status and outcome variables in fibromyalgia, as in other rheumatic disorders. Assessments that can be useful routinely to clinicians include measurements of pain, fatigue, physical function, sleep quality, anxiety, depression, and work status. At minimum, assessments should include visual analog scales (VAS) for pain and fatigue and a measure of functional status. Function can be assessed by one of the family of health assessment questionnaires including the Health Assessment Questionnaire (HAQ),⁴⁷ the Health Assessment Questionnaire–II (HAQ-II),⁴⁸ and the Multidimensional Health Assessment Questionnaire (MDHAQ).⁴⁹ The HAQ is a 33-item questionnaire; the function scale of the HAQ-II and MDHAQ is a 10-item questionnaire. Simple scales for the assessment of anxiety, depression, and sleep disturbance also can be added. For simplicity and ease of administration, however, we recommend VAS assessments of pain and fatigue and either the HAQ-II or MDHAQ.

The Fibromyalgia Impact Questionnaire (FIQ) is a widely used 21-item research assessment scale that addresses all of the key fibromyalgia variables and can be used in clinical care.⁵⁰⁻⁵² The limitation of the FIQ is that it is suitable only for use in fibromyalgia patients, whereas the previously mentioned health assessment questionnaires are useful and have been used across the entire range of rheumatic disorders. In addition, the FIQ total scale has no simple interpretation.

Functional questionnaire results have reduced validity among fibromyalgia patients. Compared with patients with rheumatoid arthritis and ankylosing spondylitis, there was striking discordance between observed and questionnaire-reported activities in patients with fibromyalgia.⁵³ This discordance limits slightly the usefulness of functional questionnaires and alters their interpretation: Results may represent perceived rather than actual functional difficulties.

Research Questionnaires

The Outcome Measures in Rheumatoid Arthritis Clinical Trial committee has recommended research domains and

questionnaires for fibromyalgia clinical trials.⁵⁴ These domains include pain, fatigue, sleep, depression, physical function, quality of life and multidimensional function, patient's global impression of change, tenderness, dyscognition, anxiety, and stiffness. The recommendations include use of the FIQ and the Medical Outcomes Scale SF-36.^{55,56} A recent study using observational data has shown that pain, HAQ, and fatigue explained more than 50% of fibromyalgia severity variance⁵⁷ and that the main determinants of global severity and health-related quality of life in fibromyalgia are pain, function, and fatigue. On the basis of the ACR 2010 preliminary diagnostic criteria, criteria and survey assessments have been developed.¹⁴ The Symptom Intensity Scale, which combines the Widespread Pain Index and a VAS fatigue scale, is another self-report measure of fibromyalgia severity that is suitable for clinical and survey research.⁴⁵

Physical Measures

With the exception of the performance of the tender point examination, the physical examination of a patient suspected to have fibromyalgia does not differ from the examination of any other rheumatic disease patient or pain patient. Measurement of pain threshold by the tender point examination is the only routinely useful physical measurement. Although helpful for diagnosis using the ACR 1990 classification criteria (see Table 52-2), the tender point count is poorly correlated with other fibromyalgia symptoms and with change in symptom severity among fibromyalgia patients.⁵⁸ Patients may improve or worsen substantially without important differences in the tender point count.

How to Perform the Tender Point Examination

Fibromyalgia patients have a lower threshold for pain than do subjects without fibromyalgia.⁵⁹ In the clinic, two methods exist by which tenderness can be elicited and measured⁶⁰—digital palpation and dolorimetry.⁶¹ Tender point sites represent specific areas of muscle, tendon, and fat pads that are much more tender to palpation than surrounding sites. Sites selected as part of ACR 1990 criteria⁴ represent tender point sites that best discriminate between patients with and without fibromyalgia. To test for pain with digital palpation, the ACR 1990 criteria indicate that the examiner should press the tender point site with an approximate force of 4 kg. Usually the second and third fingers or the thumb is used for palpation, and a rolling motion is helpful in eliciting tenderness. The amount of force that the examiner uses is important because a large force would elicit pain in a subject without fibromyalgia, whereas a small force may miss tenderness. The amount of force that does not elicit tenderness in an individual without fibromyalgia (just below the pressure pain threshold) is the correct force to use. In practice, less force is required in smaller, thinner, less-muscle individuals. The pressure used by the examiner and the examiner's interpretation of the patient's response can influence results of palpation. The best and most appropriate way to perform the tender point count is to ask the patient if the palpation is painful, accepting only a "yes" as a positive reply, regardless of facial expression or body

movement. Specifically, the frequently heard comment of patients to the digital examiner's question regarding pain, "It's tender," is a negative rather than a positive response and should be followed by another question such as, "Yes, but is it painful?"

Limitations to the Tender Point Examination

Although the tender point examination can provide clinically useful information when properly performed, it can be influenced by external factors. Physicians who believe the patient does or does not have fibromyalgia can influence the results by the amount of pressure applied. The meaning and use of the examination are widely known among physicians, patients, and patient support groups; in some circumstances where a positive or negative examination would seem to be desirable (e.g., in a disability or medicolegal examination), results might differ from those obtained during a routine examination. In addition, the tender point examination is inherently inaccurate around the "diagnostic" tender point count of 11.

Epidemiology

Most of the information about fibromyalgia is based on sampling using the ACR 1990 criteria. Fibromyalgia is diagnosed more frequently in women (9:1 ratio) in clinical studies. However, in population-based studies the female-to-male ratio is lower. A recent five-country European study noted the female-to-male ratio to be about 1.7:1,⁶² though a U.S. study found a ratio of 6.8:1⁶³ and the ratio varies from high to low in other countries.⁶²

Using ACR criteria, the prevalence of fibromyalgia in the adult general population is generally similar across the world. The prevalence of fibromyalgia in Wichita, Kansas, was 3.4% among women, 0.5% among men, and 2% overall⁶³; among women in New York City, it was 3.7%.⁶⁴ In Ontario, Canada, the estimated prevalence was 4.9% among women, 1.6% among men,⁶⁵ and 3.3% overall. The prevalence of fibromyalgia in these studies increased with age until about age 70, after which it decreased slightly. Outside of North America, reports indicate the prevalence in five European countries was 4.7% and 2.9% according to different screening methods⁶²; in studies in Bangladesh it was 5.3% to 7.5% in women and 0.2% to 1.4% in men⁶⁶; in North Pakistan, it was 2.1% overall⁶⁷; in Italy, it was 2.2%⁶⁸; in Turkey, it was 3.6% for ages 20 to 64⁶⁹; in Brazil, it was 2.5%⁷⁰; and in Southwest Sweden, it was 1.3%.⁷¹

The prevalence of fibromyalgia in children in three studies was 1.2%,⁷² 1.4%,⁷³ and 6.2%.⁷⁴ At a follow-up time of 1 year, approximately 25% of individuals meeting ACR criteria initially still satisfied the criteria.^{73,74} These data should not be interpreted as evidence of prognosis because some individuals not meeting criteria initially meet them at the 1-year follow-up. Instead, the data suggest that the concept of fibromyalgia in children may be dubious, particularly when dependent on tender point assessment. The prevalence of fibromyalgia is generally greater in clinical settings than in epidemiologic studies. It was noted to be 5.7% in general medical clinics⁷⁵ and 2.1% in family practice settings.⁷⁶ In rheumatology clinics, fibromyalgia

prevalence was expectedly higher: 12%⁷⁷ to 20%³⁰ of new patients.

The ACR 2010 criteria should result in changes in the sex ratio because men have higher pain thresholds and are therefore less likely to be diagnosed as having fibromyalgia than women when the 1990 criteria are used. The proportion of men with fibromyalgia in the community in a large German population study was 40.3%.⁷⁸ This study included criteria⁷⁹ that used the Regional Pain Scale⁸⁰ and measurement of fatigue. Diagnosis by this method yields results that are similar to survey modifications on the ACR 2010 preliminary criteria.¹⁴ The overall prevalence in the German study was 3.8%.⁷⁸ Additional studies are necessary to determine the prevalence of fibromyalgia when the 2010 criteria are used.

ETIOLOGY AND PATHOPHYSIOLOGY

In the 30-year period following the establishment of the fibromyalgia case definition and criteria, there have been substantial advances in understanding mechanisms associated with fibromyalgia pain and other symptoms.⁸¹ Although most of the recent study data are robust, the interpretation of the data is often questionable and misleading. Because these research data form the basis of "scientific" support for fibromyalgia, the objections should be considered carefully and seriously. We outline some of the objection before providing the research data themselves.

1. Research data treat fibromyalgia as a disease associated with at least 11 tender points (ACR 1990 criteria definition), but it is exceedingly unlikely that the observed pathophysiologic abnormalities are confined to greater than or equal to 11 tender points because the body of clinical and epidemiologic evidence does not support a dichotomous condition. It seems likely that observed abnormalities are also found in nonfibromyalgia patients. Studies need to be performed to determine the distribution of the observed abnormalities in pain patients not satisfying the fibromyalgia classification criteria definition.
2. Almost all of the data linking the observed abnormalities to fibromyalgia are correlational, but they are often interpreted causally—a direction of causality that may be wrong. The causal path in fibromyalgia may be complex. All human processes and sensations are expressed biologically. It would be surprising not to find associations.
3. Even assuming causal associations, the explanatory power of these associations have not been described and may be weak. The noted associations do not necessarily predict development of fibromyalgia.
4. The pathogenetic associations attributed to fibromyalgia are noted in other disorders.^{82,83}
5. The literature of fibromyalgia pathogenesis is filled with inadequate proofs because authors have drawn strong conclusions from limited correlative data.
6. Selection of patients and controls can be a problem. Specifically, patients may be too "good" and control subjects represent "healthy controls" rather than other pain patients. Healthy controls will always be different from patients with illnesses.

Muscles and Microtrauma

Originally thought to be important in pathogenesis, muscle and tendon disorders have fallen out of favor because they do not explain adequately the systemic symptoms of fibromyalgia. In addition, changes found in muscle biopsy specimens are nonspecific, consistent with many types of muscle damage, ranging from ischemia to simple deconditioning, and are not different from changes found in individuals without fibromyalgia.

Genetic and Familial Factors

Compared with patients with rheumatoid arthritis, fibromyalgia aggregated strongly in families: the odds ratio measuring the odds of fibromyalgia in a relative of a proband with fibromyalgia versus the odds of fibromyalgia in a relative of a proband with rheumatoid arthritis was 8.5.⁸⁴ Genetic factors may predispose individuals to fibromyalgia.⁸¹ Patients with chronic widespread pain and fibromyalgia have been found to have low gene expression for the proinflammatory cytokines interleukin-4 and interleukin-10 and reduced levels of serum concentrations compared with controls. These findings might indicate a role for cytokines in the pathophysiology of fibromyalgia or as a sequel of chronic pain and its treatment.⁸⁵ However, a study of 31,318 twins in the Swedish Twin Registry suggested that the co-occurrence of FSS in women can be best explained by affective and sensory components in common to all these syndromes, as well as by unique influences specific to each of them, suggesting a complex view of the multifactorial pathogenesis of these illnesses.⁸³

Psychosocial Factors

Psychosocial factors, which include reduced education, nonmarried status, lower household income, smoking, and obesity, have been identified in many studies. The chicken or egg question remains.⁸²

There has been disagreement as to whether psychiatric abnormalities represent reactions to chronic pain or whether the symptoms of fibromyalgia are a reflection of psychiatric disturbance. Psychiatric disorders may interact with the neuroendocrine system as part of a stress reaction.⁴⁴ The most common psychiatric conditions observed in patients with fibromyalgia include depression, dysthymia, panic disorder, and simple phobia.⁸⁶ In the National Data Bank for Rheumatic Diseases 64% of patients report prior depression, and 8% report mental illness. Fibromyalgia also occurs in patients without significant psychiatric problems, however. Some individuals with fibromyalgia satisfy the American Psychiatric Association criteria for somatoform disorders (DSM 307.80 and 307.89).⁸⁷

Sleep Disturbance

Fibromyalgia patients often report unrefreshing and non-restorative sleep.⁸⁸ Electroencephalographic abnormalities initially were thought to play a major role in the pathogenesis of fibromyalgia, but it is now clear that such abnormalities are nonspecific findings. Sleep electroencephalographic studies show abnormalities of delta wave or stage 4 sleep by

repeated alpha wave intrusion. Similar abnormalities are found in healthy individuals and in individuals with emotional stress, fever, osteoarthritis, rheumatoid arthritis, and Sjögren's syndrome.

Stress-Related Neuroendocrine Dysfunction

Stress responses and endocrine axes are disturbed in fibromyalgia, but many of these changes are commonly seen in patients who have known external sources of chronic pain. It is unclear whether these endocrine disturbances in fibromyalgia are primary to the disorder or are secondary to the pain or distress associated with fibromyalgia. Patients with fibromyalgia report more past stressful life events and more daily stressful hassles than patients with rheumatoid arthritis or pain-free healthy controls. Similarly, fibromyalgia is associated with increased reports of virus and other infections (Epstein-Barr virus, parvovirus, Lyme disease); hormonal alterations such as hypothyroidism; and catastrophic events where the patient is the victim of actions of others (e.g., war, car accidents) but not natural disaster⁵⁸ preceding fibromyalgia; and a higher frequency of sexual abuse in childhood. Work-related psychologic factors such as work demands and factors such as job control, social support, and psychologic distress are associated with reporting of musculoskeletal pain, particularly when pain is reported at multiple sites.⁸⁹

Primary Neuroendocrine Dysregulation

Primary neuroendocrine dysregulation found in fibromyalgia can be divided into changes in the two major stress systems: the hypothalamic-pituitary-adrenal axis and the autonomous nervous system. In fibromyalgia, almost all hormonal feedback mechanisms controlled by the hypothalamus are disrupted. After stimulation of the hypothalamic-pituitary-adrenal axis with exogenous corticotropin-releasing hormone or by insulin-induced hypoglycemia, an exaggerated pituitary adrenocorticotrophic hormone release has been observed with relative adrenal hyporesponsiveness.⁹⁰

Serum thyroid hormone levels are normal, but after intravenous injection of thyrotropin-releasing hormone, patients with primary fibromyalgia responded with a significantly reduced secretion of thyrotropin and thyroid hormones.⁹¹ Growth hormone is secreted during stage 4 sleep and is important for muscle repair and strength. Low levels might explain extended periods of muscle pain after exertion in fibromyalgia patients. Serum growth hormone levels and levels of somatomedin C (insulin-like growth factor-I) have often been reported to be low, but results are inconsistent.⁹² It is possible that physical deconditioning, related to avoidance of physical activities because of pain, could lead to more fatigue, stiffness, and, via altered growth hormone metabolism, sleep disturbance.

Autonomous Nervous System

Sympathetic function in fibromyalgia patients has been reported as low, normal, or functionally high. There is a derangement of sympathetic tone and reaction in some patients, being high or low, depending on the situation. One

explanation for this finding may be that most studies did not control for physical activity levels of participants.⁹³ It has also been suggested that fibromyalgia is a generalized form of complex regional pain syndromes such as reflex sympathetic dystrophy.⁹⁴

Abnormal Pain Processing

There are major differences between the sexes with respect to analgesic responses, across all animal species. This may explain the decreased pain tolerance in women with fibromyalgia compared with men. Patients with fibromyalgia have reduced pain tolerance to stimuli that are normally not painful such as pressure, heat, and electric pulse, at the classic tender points and control points (allodynia). They also perceive pain as being more intense and extending for a longer time (hyperalgesia).

This abnormal sensory pain processing could be explained by increased pain facilitation and reduced pain-inhibiting mechanisms on the spinal and cerebral levels. Fibromyalgia patients also displayed abnormal temporal summation of pain after a series of thermal stimulations, called “wind-up.”⁹⁵

The concentration of substance P, a neuromodulator of pain, in the cerebrospinal fluid was threefold greater in fibromyalgia patients than in controls. Substance P may play a role in spreading of muscle pain. This elevation of substance P is not specific to fibromyalgia, however, and has been shown in patients with pain due to other causes. Measures of pain intensity in fibromyalgia patients are correlated with levels of metabolites of the excitatory amino acid neurotransmitters glutamate and aspartate. Sensitization of nociceptive neurons in the spinal dorsal horn by hyperexcitable receptors such as the glutamate receptor *N*-methyl-D-aspartate could be one of the mechanisms responsible for pain in fibromyalgia.⁹⁶

Decreased Pain Inhibition

Pain inhibitory pathways, descending from the cortex, limbic system, hypothalamus, thalamus, and brain stem, modulate the activity of spinal nociceptive neurons. In fibromyalgia patients, regional blood flow seems to be reduced in the most important pain processing areas in the brain, the thalamus and caudatum, compared with controls.⁹⁷

Serotonin is a neurotransmitter in the descending inhibitory pathways that inhibits release of substance P and excitatory amino acids from the terminals of primary afferent neurons. Serotonin also regulates nonrapid eye movement sleep. Low levels of serotonin metabolites have been reported in the cerebrospinal fluid and serum of patients with fibromyalgia and low back pain.⁹⁶ Serotonin antibodies are found in fibromyalgia patients four times as frequently as in controls. Although serotonin antibodies have no diagnostic relevance, they could potentially play a role in pathogenesis.⁹⁸ The role of serotonin in the pathophysiology of fibromyalgia is unclear. Drugs that affect serotonin metabolism or action do not have a dramatic effect.

Concentrations of enkephalins in the cerebrospinal fluid are roughly twice as high in fibromyalgia and idiopathic low back pain patients, consistent (but not pathognomonic) with the hypothesis that there is increased release of endogenous mu opioid ligands in fibromyalgia, leading to

high baseline occupancy of the receptors. This is consistent with the anecdotal clinical experience that opioids are generally ineffective analgesics in patients with fibromyalgia.⁵⁸

CENTRAL NERVOUS SYSTEM (CNS) INVOLVEMENT IN FIBROMYALGIA SYNDROME

Proton Magnetic Resonance Spectroscopy and Functional Brain Imaging in Assessment of CNS Involvement in Fibromyalgia

Why Search in the Brain For an Explanation of the Riddle of Fibromyalgia?

Fibromyalgia is complex and variably expressed but almost always features some degree of pain amplification. Interestingly, this hyperalgesia is not confined to pressure stimuli but also involves heightened responses to heat, noise, and smell, suggesting an important role for central pain processing abnormalities.⁹⁹ Although the pathology of fibromyalgia is poorly understood, a growing body of evidence suggests involvement of the CNS. The hippocampus is a brain center that is sensitive to the effects of stress exposure and has been demonstrated to be affected in a variety of disorders that, like fibromyalgia, began with a stressful experience.¹⁰⁰

Ultimately, there is central sensitization to pain in which low-intensity stimuli in peripheral tissues such as skin and muscle generate an exaggerated nociceptive response that is interpreted centrally as pain. The central mechanisms underlying this amplified pain perception have been explored using a number of advanced imaging techniques that aim to localize and characterize abnormalities in specific areas of the brain called the pain “matrix.”¹⁰¹

ADVANCED IMAGING TECHNIQUES

Studies with single photon emission computed tomography, using injected radioactive compounds in the bloodstream that decay over time, have reported an abnormal reduction of regional cerebral blood flow in thalamic and caudate nuclei of patients with fibromyalgia during rest.^{97,102} In two other studies that used functional magnetic resonance imaging, fibromyalgia patients exhibited enhanced responses to painful and nonpainful stimulation in multiple areas of the brain such as the somatosensory cortices, insula, putamen, anterior cingulate cortex, and cerebellum, as compared with healthy control subjects.^{103,104} These findings were consistent with a left shift in the stimulus-response function, which is characteristic of centrally mediated hyperalgesia and reduced noxious threshold to sensory stimuli.⁸¹

Hippocampus Dysfunction in Fibromyalgia and Neurometabolic Assessment by Proton Magnetic Resonance Spectroscopy

The hippocampus plays crucial roles in maintenance of cognitive functions, sleep regulation, and pain perception, and in studies using single-voxel magnetic resonance

spectroscopy, metabolic dysfunction of the hippocampus was found in fibromyalgia patients.^{105,106} Others found proton magnetic resonance spectroscopy abnormalities at the basal ganglia and the supraventricular white matter and right dorsolateral prefrontal cortex.¹⁰⁷

Gray matter loss in fibromyalgia patients was suggested by magnetic resonance voxel-based morphometric analysis.¹⁰⁸ In this study fibromyalgia patients had significantly less total gray matter volume and showed a 3.3 times greater age-associated decrease in gray matter than healthy controls. The longer the individuals had had fibromyalgia, the greater the gray matter loss, with each year of fibromyalgia being equivalent to 9.5 times the loss in normal aging. In addition, fibromyalgia patients demonstrated significantly less gray matter density than healthy controls in several brain regions including the cingulate, insular, and medial frontal cortices and parahippocampal gyri.¹⁰⁸ In particular, fibromyalgia appears to be associated with an acceleration of age-related changes in the very substance of the brain. Moreover, the regions in which objective changes are demonstrated may be functionally linked to core features of the disorder including affective disturbances and chronic widespread pain.

Sensory Gating and Reduced Brain Habituation to Somatosensory Stimulation in Patients with Fibromyalgia

The attenuation effect of the event-related brain responses following stimulus repetition in healthy subjects is a well-known psychophysiologic phenomenon called *sensory gating*.^{109,110} Montoya and colleagues examined brain activity elicited by repetitive nonpainful stimulation in patients with fibromyalgia in order to determine possible psychophysiologic abnormalities in their ability to inhibit irrelevant sensory information. Their findings suggest that in fibromyalgia patients, there is abnormal information processing, which may be characterized by a lack of inhibitory control to repetitive nonpainful somatosensory information during stimulus coding and cognitive evaluation. These data further extend previous findings¹¹¹⁻¹¹³ of an abnormal brain processing of nonpainful somatosensory information, rather than a generalized information processing dysfunction, in patients with fibromyalgia.¹¹⁰

Deficits of Nociceptive Information Processing

In this regard, findings of Montoya and colleagues¹¹⁴ add to a growing literature in which fibromyalgia patients have been shown to have some deficits of nociceptive information processing relative to healthy controls such as enhanced sensitivity to repetitive pain pressure, abnormal maintenance of pain sensations after repetitive thermal stimulation,^{115,116} or deficits in the endogenous pain inhibitory system.¹¹⁷ In another work Wood and colleagues¹¹⁸ investigated presynaptic dopaminergic function in six female fibromyalgia patients in comparison with eight age- and sex-matched controls as assessed by positron emission tomography (PET) with 6-fluoro-L-DOPA as a tracer. Their findings indicate a disruption of presynaptic dopamine activity wherein dopamine plays a putative role in natural

analgesia. Harris and colleagues¹¹⁹ demonstrated by PET decreased mu opioid receptor availability in fibromyalgia.

Further, it has been suggested that hyperalgesia and allodynia in fibromyalgia, as well as in other chronic pain states, are the behavioral consequences of central sensitization. Thus it would be possible that the observed disruption of the inhibitory brain mechanism involved in the early processing of non-nociceptive repetitive stimulation might be a further consequence of those neuroplastic changes due to central sensitization associated with chronic pain.¹¹⁰

These findings indicate that central factors are important in the processing of pain in people with fibromyalgia. The neuroimaging findings are highly consistent with studies done in pain more generally.¹²⁰ These findings suggest that individuals with fibromyalgia have a narrow range of tolerance for pain and perhaps other sensory stimuli, before it becomes noxious.⁵⁸

MANAGEMENT OF FIBROMYALGIA: RESEARCH STUDIES AND RECOMMENDATIONS

The value of contemporary treatment can be gauged by review of outcome studies. Fibromyalgia outcome has been the subject of a number of reports, usually in small studies encompassing short periods of time. In general, results of these studies tend to suggest little change in symptoms, suggesting a limited effect of treatment. Most long-term observational studies do not show improvement in fibromyalgia symptoms and outcomes, even when patients are followed in centers with special interest and knowledge of fibromyalgia.^{121,122} In a recent longitudinal study, 1555 patients displayed continuous high levels of self-reported symptoms and distress despite treatment over a mean of 4 years of follow-up. Service utilization (a measure of symptom activity) does not lessen after diagnosis.¹²³ Benefit of treatment is generally not sustained in long-term randomized clinical trials.^{124,125} These data should be kept in mind when evaluating the results of treatment clinical trials. The null hypothesis for a chronic, painful disorder should not be no short-term treatment effect, but instead no long-term treatment effect. Short-term studies should be regarded with suspicion, and most fibromyalgia studies are short term.

Compliance with treatment is an important problem in fibromyalgia, and in fibromyalgia clinical trials the dropout rate is high. Even when intention-to-treat analyses are performed, the effectiveness of treatment is overestimated. Patients who follow exercise recommendations have better outcomes than patients who do not; however, most patients in clinical practice do not or will not perform aerobic exercises. It is fair to conclude that exercise prescription is often an ineffective recommendation, rather than concluding that it is an effective treatment.

Treatment trials without a true, contemporaneous control group cannot provide meaningful estimates of efficacy because they often exaggerate efficacy. In evaluating study results, the degree of improvement must be examined and the degree of improvement must be clinically meaningful. Even when improvement is clinically meaningful, the

baseline and final outcome values such as values of pain and fatigue must be considered. If the patients are selected for trials in relative (temporary) flare conditions, they may improve “significantly” but still have high levels of the outcome variables at the conclusion of the trial.

Numerous useful reviews of the short-term treatment in fibromyalgia are available.¹²⁶⁻¹³⁴ Most such reviews rely on the concept of efficacy and rank evidence as a function of study quality. One review indicates that “evidence for treatment efficacy was ranked as strong (positive results from a meta-analysis or consistently positive results from more than one randomized controlled trial [RCT]), moderate (positive results from one RCT or largely positive results from multiple RCTs or consistently positive results from multiple non-RCT studies), and weak (positive results from descriptive and case studies, inconsistent results from RCTs, or both).”¹²⁶ As noted by these authors, studies are necessary “... to determine whether the improvement is maintained over months or years.” Recent meta-analyses have included measurements of standardized mean differences (effect sizes)¹²⁷⁻¹³⁴ but still do not assess long-term benefit.

Still another problem with the interpretation of fibromyalgia studies relates to study scales. Because patients diagnosed as having fibromyalgia have problems with pain, fatigue, cognition, and anxiety and depression, to name some issues in fibromyalgia, studies may select different scales and outcomes according to the interests of the investigators. This leads to problems in comparing study results. In addition, when multiple outcomes and study instruments are selected, frequently studies can show positive results for one outcome and negative results for another. Even when an outcome such as pain is being measured, if there is more than one pain scale, positive results may be found with one pain scale and not with another. Complex scales are also difficult to interpret, as is the case with the commonly used FIQ total scale. This composite summary scale has no simple interpretation: A reader may note an improvement but not have a clear idea of what such improvement means.

From 6750 fibromyalgia patients screened in the National Data Bank for Rheumatic Diseases, the mean (standard deviation) VAS pain and fatigue scores were 6.3 (2.5) and 7.0 (2.5). As an aid in interpreting effect sizes, the following data are presented; assuming a baseline score of 7.0 on a 0 to 10 VAS scale, the following are the effect size, change score, post-treatment score, and percent improvement at the last assessment: 0.3, 0.75, 6.25, 10.7%; 0.4, 1.25, 6.0, 14.3%; 0.5, 1.25, 5.75, 17.9%; 0.6, 1.5, 5.5, 21.4%.

Finally, the main limitations of results and inferences from fibromyalgia clinical trials is that they cannot be extrapolated to patients in practice because of the artificial nature of clinical trials, issues of compliance, and absence of long-term results.

Häuser and colleagues¹³⁵ have provided a detailed compendium of the full range of fibromyalgia therapy, citing research evidence and committee recommendations. In making recommendations for therapy, these reviewers also considered costs and adverse effects. Readers should find this review particularly helpful, although they should keep in mind the degree of observed benefit, its persistence, and other issues mentioned earlier.

Diagnosis

Diagnosis may be an important aspect of treatment. Diagnosing fibromyalgia in individuals with short-term stress-related illnesses is harmful and leads to prolonged illness and medicalization. No valid evidence supports the assertion that diagnosis of fibromyalgia in patients with long-term symptoms has a salutary effect. A study of primary care patients in the United Kingdom reported that “... patients who had been diagnosed as having [fibromyalgia] reported higher rates of illness and health care resource use for at least 10 years prior to their diagnosis, which suggests that illness behavior may play a role. ... Diagnosis has a limited impact on health care resource use in the longer term, possibly because there is little effective treatment.”¹³⁶

At the patient level, there is no evidence that diagnosis is harmful. Using the diagnostic term in the presence of severe symptoms often makes it easier for physicians and patients to discuss the condition; when fibromyalgia is not diagnosed, patients sometimes ask directly, “Do I have fibromyalgia?” In considering making the diagnosis of fibromyalgia, the physician should consider the following comment by Barsky and Borus⁶: “The hyperbole, litigation, compensation, and self-interested advocacy surrounding the FSS can exacerbate and perpetuate symptoms, heighten fears and concerns, prolong disability, and reinforce the sick role. Excessive medical testing and treatment expose patients to iatrogenic harm and amplify symptoms.” But if fibromyalgia is “diagnosed,” it is important to be clear to the patient that fibromyalgia is a name given to the symptoms, not a cause of the symptoms.

When a fibromyalgia diagnosis is applied to the larger community, rather than at the level of the individual patient, it has been suggested that a virulent idea and a maladaptive social construction of disease such as fibromyalgia can induce and sustain illness in susceptible persons: a psychosomatic meme, acting as a transmissible template.¹³⁷ Direct-to-patient advertising and disease mongering by drug companies expand the definition of fibromyalgia and recruit patients to the diagnosis, offering support to this idea.

Education

Education in some reports may have a modest effect on fibromyalgia symptoms such as fatigue, anxiety, and depression but has limited to no effect on pain.^{138,139} What is called *education* is actually composed of two components—education and rapport or engagement—and it is impossible to distinguish the two components. Most education studies are derived from formal university-based treatment programs; only one study was applicable to clinical practice,¹³⁹ and the sample size was too small to evaluate the effect of the intervention in fibromyalgia. All studies had deficiencies in the validity of the control groups; there are no long-term data on the effect of education. Although it is sensible that education should always be part of any treatment program and is part of establishing rapport, its content should depend on the patient, the duration of illness, and the diagnostic label already present. The goal of education is to help the patient understand and manage his or her

symptoms optimally, reduce dependence on the medical system, and work effectively within that system when necessary. There are no data, however, as to whether, within the clinical setting, extensive education is more or less effective than limited education. In a group of 100 consecutive enrollees in a 1.5-day multidisciplinary group outpatient fibromyalgia treatment program, after 30 days a 12.8% improvement was noted in the 78 who completed the study.¹⁴⁰

Exercise

Aerobic exercise increases cardiovascular fitness and reduces pain and other fibromyalgia symptoms. In a short-term RCT, exercise improved aerobic performance by 16% and pain by 13%.¹⁴¹ A carefully done, well-powered RCT of a 12-week community-based exercise program compared with relaxation controls showed a 4% difference in FIQ scores at 1 year but nonsignificant changes in McGill pain scores and SF-36 scores.¹⁴² At the 12-month follow-up, 38% of subjects in the exercise arm and 22% in the control arm rated themselves much better or very much better. Only 53% of patients attended more than half of the intervention sessions. A follow-up report at 12 months on patients who participated in a 23-week, three-times-per-week exercise program indicated general improvement compared with baseline values.¹⁴³ The degree of improvement as measured by the FIQ was 5%.

The Cochrane collaboration evaluated 34 studies that included exercise, noting that there is moderate-quality evidence that aerobic-only exercise training at recommended intensity levels has positive effects on global well-being (standard mean difference [SMD], 0.49) and physical function (SMD, 0.66) and possibly on pain. The researchers concluded that “supervised aerobic exercise training has beneficial effects on physical capacity and fibromyalgia symptoms.”¹⁴⁴ A noncontrolled study comparing water-based exercise with land-based exercise showed an average 36% reduction in pain.¹⁴⁵ Exclusions in this study included 67 for work schedule incompatibility and 32 for nonspecified refusals; 60 patients were randomly assigned, and 52 completed the study.

Practically, the problem with exercise prescription is that it is difficult to get fibromyalgia patients to participate. Exercise may produce “short-term increases in pain and fatigue that should abate within the first few weeks of exercising,”¹⁴⁶ but this may be unacceptable to patients in ordinary clinical settings. Even in formal programs, adherence to exercise is poor.^{147,148} In a 4.5-year follow-up of a randomized trial of exercise, only 20% of patients maintained an adequate physical activity level.¹⁴⁹ In the National Data Bank for Rheumatic Diseases from 1999 to 2010, 16% of 3115 fibromyalgia patients reported performing some aerobic exercise weekly, but only 5% performed at levels substantial enough to result in increasing or maintaining aerobic fitness.

Cognitive Behavioral Therapy

Cognitive behavioral therapy is a form of short-term, goal-oriented psychotherapy. It has been the subject of some positive reports,¹⁵⁰⁻¹⁵⁴ some less positive reports,^{124,155,156} and some completely negative studies.¹⁵⁷⁻¹⁵⁹

Pharmacotherapy

Analgesics and Nonsteroidal Anti-inflammatory Drugs

Many drugs frequently used by patients diagnosed as having fibromyalgia have not been formally evaluated for efficacy or effectiveness.¹²⁶ With respect to analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs), a 1998 multicenter study of 538 fibromyalgia patients noted the following usage in a 6-month period: aspirin, 20.6%; NSAIDs, 55.9%; acetaminophen, 27.6%; strong opioid analgesics, 6.4%; and nonopioid analgesics, 21.5%.¹⁶⁰ Tramadol use was 15%. Tramadol use remained at 15% in 2010 in the National Data Bank for Rheumatic Diseases. These data, showing the substantial use of NSAIDs, are important because it is often suggested that NSAIDs are ineffective.¹²⁶

A few analgesic and NSAID treatments have been formally evaluated. Naproxen, 500 mg twice daily (n = approximately 15), which is the only NSAID that has been studied, was indistinguishable from placebo (n = approximately 15) in a controlled clinical trial of relatively young subjects (age 48 years).¹⁶¹ The combination of tramadol and acetaminophen reduced pain 18.5% more than did the use of placebo.¹⁶² In this trial, 48% in the active treatment group and 62% of placebo users were noncompleters in this 3-month trial.

Psychotropic Agents

Many drugs that have antidepressant and other psychotropic attributes have been used in fibromyalgia treatment. Such drugs reduce pain centrally, even in the absence of depression, and may be employed at doses that are insufficient to treat depression. Because of the many different trials and classes of drugs studied, meta-analyses have provided a useful overall overview.^{129,163,164} We summarize the results of Häuser and colleagues.¹²⁹ In their meta-analysis of 18 RCTs (1427 participants), there was strong evidence for an association of antidepressants with reduction in pain (SMD, 0.43); fatigue (SMD, 0.13); depressed mood (SMD, .26); and sleep disturbances (SMD, 0.32).

The major classes of drugs included tricyclic and tetracyclic antidepressants (TCAs): amitriptyline and nortriptyline; selective serotonin reuptake inhibitors (SSRIs): paroxetine, fluoxetine, and citalopram; serotonin and noradrenaline reuptake inhibitors (SNRIs): duloxetine, milnacipran; and monoamine oxidase inhibitors (MAOIs): moclobemide and pirlindole. In subanalysis by class, effect sizes for pain reduction were large for TCAs (SMD, 1.64); medium for MAOIs (SMD, 0.54); and small for SSRIs (SMD, 0.39) and SNRIs (SMD, 0.36). Similar, although slightly weaker, results are noted with cyclobenzaprine.

Compared with clinical trial results, results in longitudinal studies and clinical practice show marginal effectiveness of tricyclic antidepressants and similar treatments. A high-quality RCT found no difference in the response to amitriptyline and cyclobenzaprine.¹⁶⁵

Other Pharmacologic Treatments

On the basis of clinical trial criterion for efficacy, there is no evidence for efficacy of NSAIDs, corticosteroids, benzodiazepine and nonbenzodiazepine hypnotics, guaifenesin,

melatonin, calcitonin, opioids, thyroid hormone, dehydroepiandrosterone and magnesium, or anti-tumor necrosis factor therapy.¹²⁶

Nonpharmacologic Treatments

There is some evidence for efficacy of numerous nonmainstream treatments including strength training^{127,149,166} and hypnosis.¹⁶⁷ There is weak evidence for chiropractic, manual, and massage therapy and no evidence of efficacy for tender or trigger point injections or flexibility exercise. Evidence for acupuncture is contradictory,^{168,169} as is evidence for the efficacy of biofeedback¹⁷⁰⁻¹⁷² and balneotherapy.¹⁷³⁻¹⁷⁵ Local injections in muscular areas of pain are also commonly employed by rheumatologists. The authors surveyed rheumatologists regarding the use of injections and found them to be used frequently, in agreement with others.¹²⁶ Rheumatologists reported that patients “like injections,” but also that the rheumatologists did not know what else to do. A comprehensive review of nonpharmacologic therapies is available.¹⁷⁶

Combination Therapy

Although most studies reported earlier concern monotherapy, in practice most fibromyalgia treatments combine multiple therapies. Ordinarily these treatment regimens use analgesics, antidepressants, education, and exercise (at least, exercise recommendations). The extent to which several or many therapies is superior to one or few therapies is not clear. But the effect seems small. So one cannot simply add effect sizes of individual therapies to gauge the multitherapy effect.

A meta-analysis of multicomponent treatment in RCTs (at least one educational or other psychologic therapy with at least one exercise therapy) included nine RCTs with 1119 patients.¹²⁸ The authors reported: “There was strong evidence that multicomponent treatment reduces pain (SMD, 0.37); fatigue (WMD, 0.85); depressive symptoms (SMD, 0.67); and limitations to health-related quality of life (HRQOL) (SMD, 0.59) and improves self-efficacy pain (SMD, 0.54) and physical fitness (SMD, 0.30) at post-treatment. There was no evidence of its efficacy on pain, fatigue, sleep disturbances, depressive symptoms, HRQOL, or self-efficacy pain in the long term. There was strong evidence that positive effects on physical fitness (SMD, 0.30) can be maintained in the long term (median follow-up 7 months).” Overall, these data indicated increased benefits of multicomponent treatment as defined here, compared with “other” therapies. But the benefit is still modest and cannot be clearly extrapolated to the long term.

Practical Recommendations in the Approach to a Patient with Fibromyalgia

The goal of fibromyalgia treatment is to improve the physical and mental health of patients and their quality of life. This goal implies helping patients manage distressing symptoms, but with decreased dependence on the medical care system. There are no studies as to how often the simple recommendations of education, exercise, and limited pharmacologic treatment provide results at an acceptable level

of symptoms and functional ability. Data from the National Data Bank for Rheumatic Diseases show, however, that 61% of 3276 fibromyalgia patients observed from 1998 to 2010 were somewhat or very dissatisfied with their health compared with 35% of 24,891 patients with rheumatoid arthritis. These data indicate that contemporary treatment of fibromyalgia is generally unsatisfactory.

This high level of dissatisfaction is reflected in physician and patient interactions. An unknown but probably small proportion of rheumatology experts refuse to accept referral of fibromyalgia patients. A larger proportion is unhappy seeing such patients or is uncomfortable providing care. Patients, sensing this attitude, are equally unhappy with physicians: Patient support groups provide specific advice on finding positive, sympathetic physicians including identifying them by name. Physician behavior results from a general uncomfortableness with illnesses that are often unresponsive to treatment and have strong psychologic and psychosocial components. There is no simple resolution to this problem. Physicians who are unable to provide helpful care to patients with fibromyalgia should make that known to the patients.

Interest in fibromyalgia and drug company support has resulted in extensive studies of treatment,¹²⁷ often with recommendations for treatment.¹²⁷ The practical result of applying recommendations based on short-term clinical trials to an often poorly responsive chronic illness is uncertain because there is as yet no evidence of long-term effectiveness of treatment. In the face of ineffectiveness, treatment recommendations can lead to switching from one therapy to the next and increased medicalization.

In considering fibromyalgia treatment, physicians should determine what resources are available in the community, and whether the resources are effective and helpful. The educational, exercise, and cognitive behavioral therapy programs described in the research studies earlier are often not available to U.S. community physicians. Available programs may or may not be competent, appropriate, or helpful. Pain management programs sometimes mean little more than spinal blocks and “trigger point” injections, and physical therapy referral often results in treatments that are ineffective for fibromyalgia. The referring physicians should investigate the quality and outcomes of referral resources.

Although the common recommendations of education, exercise, and pharmacotherapy are often appropriate, particularly in newly diagnosed cases, patients with established fibromyalgia have often experienced these recommendations and treatments. Whether such treatments have strong evidence for effectiveness or not, as measured by clinical trials, they are often not clinically effective enough, and patients return to the physician for additional suggestions and care.

The European League Against Rheumatism (EULAR) task force points out, on the basis of limited evidence¹²⁷ and consensus recommendation, that full understanding of fibromyalgia requires comprehensive assessment of pain, function, and psychosocial context. Fibromyalgia should be recognized as a complex and heterogeneous condition where there is abnormal pain processing and other secondary features. Optimal treatment requires a multidisciplinary approach with a combination of nonpharmacologic and pharmacologic treatment modalities tailored according to

pain intensity; function; and associated features such as depression, fatigue, and sleep disturbance in discussion with the patient.

The question arises as to how to approach a resistant patient with fibromyalgia, given the knowledge that after failure with several standard treatments, success with other medications is unlikely. Should the physician simply go from one (dubious) treatment to another? Should the physician use treatments of dubious or uncertain value? The adverse effects of inappropriate or unnecessary treatments are not inconsequential and include dependence, medicalization of common symptoms, overuse of medical care, increased costs, and side effects. One point of importance is that the physician should at least measure pain using a VAS scale. A similar simple measure is available for fatigue. One really cannot know how the patient is doing without such measurements.

The physician must be friendly and interested—a resource the patient can rely on. Testing should be limited and reserved for times when it is truly necessary to investigate comorbid conditions. Comorbid conditions such as arthritis and obesity should be treated because they can contribute to increasing physical and mental symptoms. The worst problem should be identified. Sometimes identifying where the pain problem began can offer clues to appropriate treatment of the coexisting condition. If many fibromyalgia treatments have been tried and have been unsuccessful, it is generally not a good idea to try even more similar, and soon to be unsuccessful, therapies. We often ask patients, “Which treatment has been most helpful?” and suggest (assuming treatment is necessary and helped at all) that they return to that treatment.

There is no blanket rule on the use of opioids. Experience has shown that they often do not truly help and often cause problems. Strong opioids are generally not recommended.¹²⁷ There are exceptions to this recommendation, however, and physicians should exercise clinical judgment and use opioids when they think such therapy is necessary, provided that appropriate guidelines are followed.¹⁷⁷ “Tender points” never need injection therapy. Painful areas in muscle may respond to local injections of local anesthetics; corticosteroids are never indicated. If injections relieve pain for more than short periods of time, they may represent a reasonable therapy. In illnesses with strong psychosocial components, medically ineffective therapies can result in overall benefit to patients. The circumstances where dubious therapies might be used are limited. The physician should understand clearly why he or she is administering such therapies and what results are anticipated.

Physical Therapy and Spa Treatment

Physical therapy is not recommended because the aerobic exercise required in fibromyalgia does not usually require formal physical therapy and increases medicalization. Because medical therapy is unsatisfactory, patients find their way to alternative therapies. Some of these therapies may be helpful to individual patients such as massage, water therapy, spa treatment, and acupuncture. These therapies tend to have high cost-effectiveness ratios, and the decision to use such therapies is often best left to the patients and the reimbursement authority. That is not to say that such

treatments do not help—everything helps—but they do not help often enough and importantly enough, and some decision point is required. One important goal of therapy is to reduce medicalization and increase independence.

In Europe and the Mediterranean a long-standing tradition of spa treatments exists and many U.S. patients, especially those whose parents came from Europe, fly over to be treated. It appears that fibromyalgia patients significantly improve after different spa treatments. In a controlled study in Tunis there was a significant improvement directly after 2 weeks of treatment and after 3 months regarding general well-being, function, pain, depression, and fatigue in 58 fibromyalgia patients compared with 76 controls.^{175,178} Comparable results were seen in Turkey¹⁷⁹ and the Dead Sea in Israel.¹⁸⁰ Reviews showed good results of spa treatment and hydrotherapy regarding pain, general well-being, and tender points continuing after 14 weeks,^{181,182} and a EULAR advisory committee concluded that treatment with hot baths with or without exercises had a good effect in fibromyalgia.¹²⁷

Complementary or Alternative Treatments

There is insufficient evidence on any complementary and alternative medicine or alternative treatment, taken orally or applied topically for fibromyalgia. The small number of positive studies lack replication.

A frustrated physician may not know where to turn next in a nonresponsive patient. Should the patient be referred to a pain clinic? Sometimes such a referral is inevitable. The quality of pain clinics varies, however, and the results in fibromyalgia are often not good. The decision to refer should depend on the experience with the available clinics and the results that they have produced. In some countries, reimbursement authorities limit referrals, providing a cost-effectiveness analysis that may be alien to the physician-patient relationship.

Treatment options sort themselves out over time. Decisions that are difficult resolve. In the end, the physician who provides support and interest is a strong resource and a guide for patients with fibromyalgia, even when medical therapies are limited.

Medicolegal Issues and Fibromyalgia

Frequently, fibromyalgia becomes a medicolegal issue when an individual with fibromyalgia asserts that he or she is unable to work because of fibromyalgia. Because fibromyalgia symptoms are felt only by the patient, there are no objective medical findings to help in the disability assessment. Gaining a disability award is complex, depending on the source of payment (e.g., government vs. private insurance), the physician's belief and documentation, the availability of legal services, and the impact of the illness on the patient. Various guidelines have been suggested for evaluating disability as they apply to fibromyalgia. Determination of disability does not depend on proving the existence of fibromyalgia.

The second medicolegal issue arises when an individual claims that trauma caused him or her to develop or exacerbate fibromyalgia and that the fibromyalgia is disabling. Although it is proposed that trauma can alter the CNS

(“neural plasticity”) and cause fibromyalgia, the relationship between the severity of trauma and the report of fibromyalgia is weak. There is no way to determine scientifically if trauma causes or caused fibromyalgia. In addition, it is often difficult to establish the severity of the fibromyalgia symptoms. In reality, the relationship between trauma and disability does not require a diagnosis of fibromyalgia because symptom severity and work impairment are important, not the presence or absence of fibromyalgia.

OUTCOME OF FIBROMYALGIA

The outcome of fibromyalgia can be studied in the context of change and level of symptoms, use of services, and work disability. Many studies have addressed the issue of outcome. Some have suggested that “... knowledge of the potential reversibility of the syndrome [is] resulting in improved outcomes”¹⁸³ and that “... outcome is good with minimal intervention.”¹⁸⁴ In a prospective study of fibromyalgia patients referred to a specialty clinic, 70 of 82 were reassessed after 3 years. The returnees were generally improved (pain reduced from 6.8 to 5.4 and fatigue reduced from 6.8 to 5.7). The authors concluded that the overall outcome was favorable.¹⁸⁵ In 33 of 51 patients seen 6 to 8 years after initial participation in a fibromyalgia treatment study, pain was reduced from 6.7 to 5.3 and fatigue was reduced from 7.5 to 6.5. The authors concluded that the results of these returnees suggest a benign long-term outcome in patients with fibromyalgia.¹⁸⁶ A six-center, 7-year study of 538 patients noted that, “Although functional disability worsened slightly and health satisfaction improved slightly, measures of pain, global severity, fatigue, sleep disturbance, anxiety, depression, and health status were markedly abnormal at study initiation and were essentially unchanged over the study period. Half the patients are dissatisfied with their health, and 59% rate their health as fair or poor.”¹²² In one report of 45 of 70 patients who had participated in a 3-week trial 6 years earlier, symptoms of fibromyalgia persisted over 6 years.¹²¹ A study of prediagnosis and postdiagnosis use of services found that no changes in the high-use rates were seen over time.¹³⁶

In a longitudinal study of 1555 fibromyalgia patients during 7448 semiannual observations for up to 11 years, there was minimal improvement in symptoms. The SMDs (improvement effect sizes) between start and study completion were patient global, 0.03; pain, 0.22; sleep problems, 0.20; SF-36 PCS, 0.11; SF-36 Mental Component Summary, 0.03; and EuroQoL (EQ-5D), 0.10. These data suggested that the course of fibromyalgia was one of continuous high levels of self-reported symptoms and distress despite available treatments.¹⁸⁷

A study of 27 of 48 (56%) patients had a 2-year follow-up.¹⁸⁸ In general, the patients showed no improvement in their symptoms over the observation period, regardless of the type of therapy they had received. General satisfaction with quality of life improved, as did satisfaction regarding health status and the family situation, although the degree of pain experienced remained unchanged. In comparison with the initial examination, there was no change in either work capacity or disability-pension status.

Taken as a whole, although some patients improve, the data tend to suggest minimal improvement in most cases

despite treatment. Even among the positive studies cited, the degree of improvement is small. These data, which are representative of the actual outcome of fibromyalgia patients in practice, provide a more realistic evaluation of treatment effect than the assessments based on clinical trials.

Synovial Fluid Analyses, Synovial Biopsy, and Synovial Pathology

HANI S. EL-GABALAWY

KEY POINTS

Analysis of synovial fluid samples by leukocyte count, cytology, polarized microscopy, Gram stain, and culture provides key diagnostic information, particularly in acute monoarthritis.

Synovial biopsy performed using closed needle techniques or arthroscopy may provide valuable diagnostic information, particularly in persistent monoarthritis.

Although the histopathologic features of synovitis are generally nonspecific, some synovial diseases can be diagnosed with small synovial tissue biopsies.

Analysis of synovial tissue using immunohistology and other molecular techniques has been of great value in understanding the mechanisms of synovitis.

Sequential analysis of synovial tissue samples in the context of therapeutic trials provides unique information regarding the effects of treatment on the target organ.

Analysis of synovial fluid and synovial tissue obtained from diseased joints provides important diagnostic information in specific clinical settings, and is valuable in addressing a spectrum of research questions aimed at enhancing our understanding of the pathogenesis and mechanisms of rheumatic diseases. Many peripheral joints are readily accessible to sampling of both synovial fluid effusions and synovial tissue, although the knee is the most frequently sampled joint. The techniques used to obtain and analyze synovial fluid and tissue samples are discussed in this chapter.

SYNOVIAL FLUID ANALYSIS

Synovial Fluid in Health

Under normal conditions, a small volume of synovial fluid is present in each joint, forming a thin interface between the surfaces of the articular cartilage, and providing for friction-free movement of these surfaces. In a large joint

such as the knee, the volume of synovial fluid is estimated to be less than 5 mL. Moreover, intra-articular pressure is typically subatmospheric. Compositionally, normal synovial fluid is an ultrafiltrate of plasma to which proteins and proteoglycans are added by fibroblast-like synoviocytes in the lining layer. Most of the small-molecular-weight solutes such as oxygen, carbon dioxide, lactate, urea, creatinine, and glucose diffuse freely through the fenestrated endothelium of the synovium and are normally present at levels comparable with those of plasma. Evidence for active transport of glucose has been found. The total protein concentration of normal synovial fluid is 1.3 g/dL. The concentration of individual plasma proteins is inversely proportional to the molecular size, with small proteins such as albumin present at approximately 50% of plasma levels, and large proteins such as fibrinogen, macroglobulins, and immunoglobulins present at low levels. It should be noted that in contrast to this selective entry on the basis of size, clearance of synovial fluid proteins through the synovial lymphatics is unrestricted by size. Hyaluronan is the major proteoglycan synthesized by synovial cells and secreted into synovial fluid. Hyaluronan is highly polymerized and reaches molecular weights exceeding one million daltons, giving this fluid its characteristic viscosity. The hyaluronan also acts to retain small molecules in the synovial fluid. The lubricating capacity of the synovial fluid is attributed to a glycoprotein called *lubricin*.¹ This molecule has been fully characterized on the basis of the study of individuals with mutations of the *PRG4* gene, which encodes for its production.² These mutations result in an autosomal recessive loss-of-function disorder called the *camptodactyly–arthropathy–coxa vara–pericarditis syndrome*, which features a progressive, noninflammatory arthropathy characterized by severe cartilage destruction associated with proliferation of synovial lining cells. The role of lubricin in maintaining the health of the cartilage has been further demonstrated in a murine knockout model.³

Accumulation of Synovial Effusions

Synovial fluid and its contents are cleared through the synovial lymphatics through a process that is aided by joint motion. Excess fluid can accumulate in any diarthrodial joint as a result of a broad range of processes, including noninflammatory, inflammatory, and septic disorders. In addition, overt hemarthroses can result from both traumatic and nontraumatic disorders. The most important mechanism contributing to the accumulation of joint effusions is an increase in synovial microvascular permeability. This allows for an increase in the efflux of plasma proteins, particularly larger proteins, which in turn increases osmotic pressure and contributes to the effusion. Leukocytes accumulate in the fluid after transmigration through the endothelium, stimulated by chemokines produced in the synovium. The capacity of synovial lymphatics to clear proteins, cells, and debris is rapidly exceeded, which in turn contributes to their accumulation in the synovial compartment.

Arthrocentesis

Most peripheral joints are readily accessible for diagnostic arthrocentesis, and the procedure can be performed in almost any ambulatory care setting equipped for sterile procedures. Joints that are less accessible because of a deeper location, such as the hip, may require an imaging technique that uses fluoroscopy or ultrasound to guide the needle and ensure accurate placement. Details of techniques used for arthrocentesis are described in Chapter 54. Because the ease with which joint fluid is aspirated depends on the gauge of the needle that is used, it is important to attempt arthrocentesis with a needle of adequate gauge, particularly in the larger joints. Moreover, high suction gradients created by

large syringes should be avoided, because they may actually reduce the capacity to successfully aspirate synovial fluid. Difficulty in aspirating synovial fluid may relate to a number of intra-articular factors, including viscosity, the presence of debris such as rice bodies, and loculation of fluid into inaccessible areas. Instillation of a small amount of sterile saline may assist in obtaining enough fluid for culture in situations where infection is highly suspected, yet direct aspiration is difficult.

Once obtained, it is important to analyze aspirated synovial fluid samples as quickly as possible to avoid spurious results. In particular, leukocyte count and differential ideally should be performed on fresh specimens. If the specimen cannot be analyzed quickly and short-term storage is needed, the specimen should be kept at 4° C, and an aliquot preferably placed in ethylenediaminetetraacetic acid (EDTA) to prevent clotting. Delays in analysis beyond 48 hours should be avoided. A simplified algorithm for analyzing synovial fluid samples is shown in Figure 53-1.

Gross Examination

First impressions regarding the nature of the synovial fluid occur as fluid enters the syringe during the arthrocentesis procedure itself. For example, the viscosity of the fluid is readily appreciated during this step. As has been mentioned, normal synovial fluid is highly viscous because of its hyaluronan content and forms a long string when a drop is expressed from the end of the needle. With increasing levels of inflammation associated with recruitment and activation of leukocytes in the synovial cavity, the hyaluronan is digested, resulting in loss of viscosity that is appreciated as a reduction in the “stringiness” of the fluid. Large pieces of debris such as rice bodies, thought to arise from detached ischemic synovial villi, may be visible as they are aspirated.

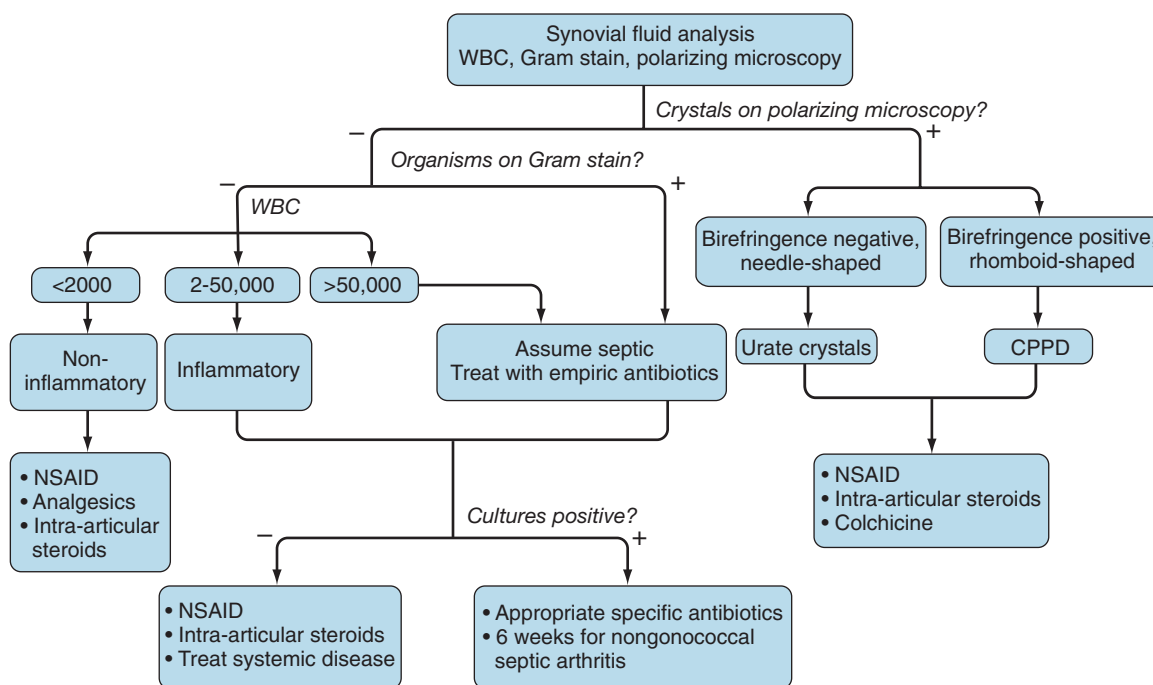

Figure 53-1 A simplified algorithm for analyzing synovial fluid samples and initiating a plan of management. CPPD, calcium pyrophosphate dihydrate; NSAID, nonsteroidal anti-inflammatory drug; WBC, white blood cell.

These can cause sudden arrests in the flow of fluid into the syringe, requiring manipulation and redirection of needle placement.

Inspection of the aspirated synovial fluid can yield other important diagnostic information. For example floridly purulent fluid will be completely opaque because of the very high number of leukocytes present, but synovial fluid that is transparent, to the point where printed text can be read through it, is seen in noninflammatory settings. Inflammatory synovial fluid, as would be aspirated from an individual with active rheumatoid arthritis (RA), appears cloudy and translucent; the degree of translucency depends on the intensity of the inflammatory response and the concentration of leukocytes in the sample. Synovial fluid from patients with ochronosis may have a speckled appearance, and particulate debris from joint prostheses may be visible on gross inspection.

During the arthrocentesis procedure, an important challenge may be to determine whether the presence of blood in the aspirated synovial fluid indicates a hemarthrosis or, alternatively, is a result of trauma from the procedure itself. In the latter case, the blood may remain unmixed with the synovial fluid, appearing as red streaks in an otherwise yellow fluid, but in the case of hemarthroses, the synovial fluid is generally homogeneously bloody and does not form a clot. The causes of frank hemarthrosis are varied and include trauma, pigmented villonodular synovitis, tumors, hemophilia and other bleeding disorders or anticoagulant therapy, Charcot joint, and occasionally intense inflammation from a chronic arthropathy such as RA or psoriatic arthritis.

Leukocyte Count

Analysis of leukocyte counts and cytology provide important diagnostic information regarding the cause of a synovial effusion (Table 53-1). A fresh specimen should be placed in a heparinized tube for rapid analysis, and if the fluid is particularly viscous, it may need to be diluted in normal saline before counting. Normal synovial fluid contains fewer than 180 nucleated cells/mm³, most of which originate as desquamated synovial lining cells. The

leukocyte count broadly classifies synovial fluids as non-inflammatory (<2000 cells/mm³), inflammatory (2000 to 50,000 cells/mm³), and septic (>50,000 cells/mm³). It should be kept in mind that these definitions provide broad guidelines to help narrow the differential diagnosis rather than representing inherent biologic properties of the fluid.

The most common causes of noninflammatory synovial fluids are mechanical derangements of the joint and osteoarthritis. Other causes include endocrinopathies such as acromegaly and hyperparathyroidism; inherited disorders such as ochronosis, hemochromatosis (which can also present with hemarthrosis), Ehlers-Danlos syndrome, Wilson's disease, and Gaucher's disease; acquired disorders such as Paget's disease, avascular necrosis, and osteochondritis dissecans; and an uncommon condition called *intermittent hydrarthrosis*, in which joints become effused in a cyclic manner. At the other extreme, leukocyte counts of 50,000 to 300,000 cells/mm³ are most commonly associated with septic arthritis and should prompt the clinician to empirically treat the individual as such until this diagnosis is excluded with a high degree of certainty, which typically requires definitive culture results, and possibly repeat aspiration. It should be added that leukocyte counts exceeding 50,000 cells/mm³ are not uncommonly seen in acute crystal-induced arthritis, particularly gout. Inflammatory cell counts between 3000 and 50,000 cells/mm³ are seen in a wide spectrum of articular disorders, including many cases of septic arthritis. Thus most patients with acute attacks of gout and pseudogout, active RA, reactive arthritis, and psoriatic arthritis, as well as patients with gonococcal arthritis and other nonpyogenic forms of septic arthritis, will typically present with synovial fluid cell counts in this range (see Table 53-1).

Synovial Fluid Cytology

Characterization of the cells present in synovial fluid is an important diagnostic step that can be achieved initially by performing cytology on a wet mount of the synovial fluid. To perform the wet mount analysis, a single drop of synovial fluid is placed on a clean glass slide, which then is covered by a coverslip and is examined under low- and high-power

Table 53-1 Characteristics of Synovial Fluid

	Appearance	Viscosity	Cells per mm ³	% PMNs	Crystals	Culture
Normal	Transparent	High	<200	<10%	Negative	Negative
Osteoarthritis	Transparent	High	200-2000	<10%	Occasional calcium pyrophosphate and hydroxyapatite crystals	Negative
Rheumatoid arthritis	Translucent	Low	2000-50,000	Variable	Negative	Negative
Psoriatic arthritis	Translucent	Low	2000-50,000	Variable	Negative	Negative
Reactive arthritis	Translucent	Low	2000-50,000	Variable	Negative	Negative
Gout	Translucent to cloudy	Low	200->50,000	>90%	Needle-shaped, negatively birefringent monosodium urate monohydrate crystals	Negative
Pseudogout	Translucent to cloudy	Low	200-50,000	>90%	Rhomboid, positively birefringent calcium pyrophosphate crystals	Negative
Bacterial arthritis	Cloudy	Variable	2000->50,000	>90%	Negative	Positive
PVNS	Hemorrhagic or brown	Low	—	—	Negative	Negative
Hemarthrosis	Hemorrhagic	Low	—	—	Negative	Negative

PMNs, polymorphonuclear neutrophils; PVNS, pigmented villonodular synovitis.

light microscopy. In addition to leukocytes, and in the case of traumatic taps or hemarthroses, or large numbers of erythrocytes, wet mount may reveal the presence of clumps of fibrin and crystals, cartilage and synovium fragments, and lipid droplets. These can all appear as amorphous material, and care should be taken to avoid assuming their composition without further characterization.

Characterization of synovial fluid leukocytes is best achieved by staining a dried smear of the fluid. Wright stain is most commonly used for this purpose. The phenotype and morphology of the leukocytes can then be assessed under high power using oil immersion. Septic range synovial fluid containing more than 50,000 cells/mm³ is almost always associated with a high preponderance of polymorphonuclear leukocytes, often greater than 90%. Monocytes and lymphocytes predominate in the synovial fluid of patients with viral arthritis, lupus, and other connective tissue diseases. Synovial fluid samples from patients with active RA, reactive arthritis, psoriatic arthritis, and acute attacks of crystal-induced arthritis typically demonstrate a preponderance of polymorphonuclear leukocytes, although early RA fluids may have a low leukocyte count with primarily mononuclear cells. The presence of large numbers of “ragocytes,” which are granulocytes that have phagocytized immune complexes, is associated with active RA, and their presence may indicate an unfavorable prognosis in this disease.⁴ Reiter’s cells represent cytophagocytic mononuclear cells that have phagocytized apoptotic polymorphonuclear leukocytes, this possibly representing a pathway by which autolysis and release of damaging mediators from the latter cells are avoided.⁵ The presence of Reiter’s cells is not specific for reactive arthritis, nor indeed for spondyloarthropathies in general. Occasionally, eosinophils will be seen to predominate in the synovial fluid. This may be associated with parasitic infection, urticaria, or hypereosinophilic syndrome. It has been suggested that cytocentrifugation of synovial fluid is the optimum method for performing cytopathology, although the cost-effectiveness of this technique is questionable in most clinical settings.

Wet Smear Analysis by Polarized Microscopy

A search for crystals using polarized microscopy is particularly valuable in the diagnosis of acute monoarthritis or oligoarthritis, in which gout and pseudogout are often on the differential diagnosis. In such a clinical situation, if indeed the absence of pathogenic crystals in synovial fluid can be established, the likelihood of septic arthritis increases, prompting the initiation of intravenous antibiotics and potentially necessitating a hospital admission. Thus, the rapid and accurate diagnosis of a crystal-induced process can serve to prevent a costly and unnecessary sequence of events. It is helpful if the individual or the team that performs the arthrocentesis is also in a position to rapidly examine the specimen by polarized microscopy. This requires the availability of a functional polarizing microscope, as well as adequate operator experience in the identification of crystals using this technique. This is particularly important in the case of calcium pyrophosphate crystals, which are notoriously difficult to detect.

Care should be taken to make sure that the slide and the coverslip are free of dust, talc, and other particulate matter.

Crystals present in the specimen rotate the light in such a way that they appear as bright objects in an otherwise dark field. It should be noted that birefringent debris frequently are scattered throughout the slide and should not be mistaken for crystals.

The first-order red compensator is usually inserted immediately below the upper filter and serves to block out green light. Birefringent material in the specimen appears as a bright yellow or blue color in the red field generated by the first-order compensator. As birefringent crystals are rotated relative to the axis of the first-order compensator, the color changes from yellow to blue or vice versa. Crystals that are yellow when oriented parallel to the axis of the compensator are negatively birefringent, and those that are blue are positively birefringent.

Identification of crystals in synovial fluid is greatly facilitated by detailed examination of the specimen, under both low and high power, using the approach previously described. A combination of morphology and birefringence serves to identify the crystals. Monosodium urate (MSU) crystals, as shown in Figure 53-2, are the easiest to identify because the crystal load is typically high during an acute attack of gout. A good degree of concordance between laboratories in the identification of MSU crystals has been shown.⁶⁻⁸ These crystals appear as strongly negatively birefringent needle-shaped objects, many of which are intracellular, having been phagocytized by synovial fluid leukocytes. In contrast, calcium pyrophosphate dihydrate (CPPD) crystals seen during attacks of pseudogout tend to be smaller, rhomboid-shaped objects that are weakly positively birefringent, as shown in Figure 53-3. Because the CPPD crystal load during an attack of pseudogout tends to be relatively low, and because CPPD crystals are only weakly birefringent, it is important to examine all areas of the specimen on the microscope slide, and possibly to prepare a second wet mount to exclude or confirm this diagnosis. Concordance between laboratories in the recognition of CPPD has been shown to be substantially lower than in the case of MSU crystals.⁶⁻⁸ A particularly challenging situation arises when intracellular crystals cannot be identified, yet birefringent extracellular objects resembling crystals are seen scattered throughout the slide. This may be caused by powder from gloves or dirt on the slides.

As with other analyses on the synovial fluid, wet mount preparation and analysis should be performed as quickly as possible, although identification of crystals can still be successful after prolonged storage of specimens. The crystal load decreases substantially as the acute inflammatory attack

Figure 53-2 **A**, Urate crystals in the tophus from a patient with gouty arthritis. Crystals are negatively birefringent and needle shaped. **B**, Intracellular urate crystal as seen on Wright stain. (Courtesy H. Ralph Schumacher, Jr.)

subside, thus making a specific diagnosis more difficult as the attack begins to subside. Urate crystals have been detected in synovial fluid between attacks of gout.

Deposits of hydroxyapatite or basic calcium phosphate are present within the joint and in periarticular locations such as around the shoulder area, and are associated with osteoarthritis. These crystals have been incriminated in a particularly destructive syndrome that has been named *Milwaukee shoulder*.⁹ Hydroxyapatite can be detected in synovial fluid, but because these crystals are generally non-birefringent, it is not possible to detect them by polarized microscopy. A useful and rapid method with which to detect hydroxyapatite and other calcium-containing crystals such as octacalcium and tricalcium phosphate is to stain the fluid with alizarin red S stain and look for clumps of crystals under routine light microscopy (Figure 53-4). These crystals have also been identified using electron microscopy, although this method is rarely available to the practicing clinician.

Synovial cholesterol crystals appear as flat, plate-like structures with notched corners (Figure 53-5), and lipid crystals have the appearance of Maltese crosses. Both can be strongly birefringent, both negatively and positively.

Figure 53-4 Clumps of calcium hydroxyapatite crystals demonstrated using alizarin red staining. Crystals are nonbirefringent. (Courtesy H. Ralph Schumacher, Jr.)

Figure 53-5 Cholesterol crystals in a synovial fluid sample. (Courtesy H. Ralph Schumacher, Jr.)

Corticosteroid crystals can be highly birefringent and mimic urate or CPPD crystals. Large amounts of lipid in the synovial fluid can be visible on gross examination. The significance of these crystals in synovial fluid is unclear, but it is unlikely that they are pathogenic in most cases.

Detection of Microorganisms by Gram Stain, Culture, and Polymerase Chain Reaction Analysis of Synovial Fluid

A wide spectrum of organisms can cause septic arthritis, although the most common pathogens are gram-positive bacteria such as staphylococci and streptococci. Because septic arthritis causes rapid destruction of the joint, and because it can spread hematogenously to other areas and is associated with significant mortality, it is imperative that a specific diagnosis be made as quickly as possible, and that empiric therapy with broad-spectrum antibiotics be instituted until this diagnosis can be confirmed or excluded.

A Gram stain performed on fresh synovial fluid will identify an organism in an estimated 50% of cases of septic arthritis,¹⁰ with highest sensitivity for gram-positive organisms. Moreover, the specificity of a positive Gram stain approaches 100%. Clearly this indicates that the positive predictive value for the Gram stain is very high, and that the negative predictive value is substantially lower. The gold standard for diagnosing septic arthritis remains bacteriologic culture, which has a sensitivity of 75% to 95% and a specificity of 90% in cases of nongonococcal septic arthritis.^{11,12} It has been shown that the use of blood culture bottles further increases the yield of positive synovial cultures.¹³ It is important to note that bacteriologic cultures are the only studies that provide a guide for specific antimicrobial therapy. Because the sensitivity of bacteriologic cultures declines dramatically after antibiotic therapy is instituted, it is important that the clinician perform arthrocentesis before any antibiotics are administered. Cultures

should be performed even when uric acid or other crystals are demonstrated in the synovial fluid, because it has been shown that gout and septic arthritis can coexist.¹⁴ In the case of gonococcal arthritis, the sensitivity of bacteriologic culture, even if performed on a sample collected using appropriate media, is low and is estimated to be less than 10%.

Polymerase chain reaction (PCR) carries a high degree of sensitivity and specificity for the detection of microorganisms in synovial fluid and tissue, even in individuals who are culture negative.¹⁵ Most bacteria can be detected on the basis of amplifying specific sequences in their ribosomal RNA (16S rRNA). PCR has been shown to be the procedure of choice for making the diagnosis of gonococcal arthritis^{16,17} and is a highly sensitive and specific method of detecting tuberculous arthritis, although as discussed later, analysis of synovial tissue is better than analysis of synovial fluid for making this diagnosis.^{18,19} PCR has also been proposed as a method of verifying the successful elimination of the offending organism in cases of septic arthritis.^{20,21}

The sensitivity and specificity of PCR in detecting synovial microorganisms need to be balanced against the biologic significance of a positive test. Contaminants are easily detected using this method, and highly stringent conditions for sample collection are required to prevent false-positive tests. Moreover, PCR studies of synovial fluid and tissue from a spectrum of chronic forms of arthritis, including RA, osteoarthritis, reactive arthritis, and undifferentiated arthritis, have indicated the presence of microorganisms in a significant number of specimens.^{22,23} The biologic significance of these findings and the potential role of bacterial DNA or cell wall fragments in the pathogenesis of these arthropathies remain unclear.

Biochemical Analysis of Synovial Fluid

A number of widely available biochemical tests may add to the diagnostic impression of aspirated synovial fluid samples, although lack of specificity of these biochemical analyses tends to limit their value.^{12,24} Testing for synovial fluid glucose, protein, and lactate dehydrogenase (LDH) has long been included in routine practice, and values obtained should be compared with serum values. Samples from septic arthritis typically exhibit very low glucose, low pH, and high lactate levels; these levels are indicative of a switch to anaerobic metabolism. Highly inflammatory synovial fluids from RA patients exhibit a similar profile, along with high protein and LDH levels. Levels of pressure of oxygen in the blood (pO₂) are often in the hypoxic range in RA synovial fluids, and are correlated with increased lactate and levels of pressure of carbon dioxide in the blood (pCO₂).^{25,26} A prospective study conducted to evaluate these tests in a spectrum of inflammatory and noninflammatory disorders demonstrated considerable variability in each diagnostic category, which limits their clinical utility.²⁴

Serologic testing of synovial fluid to detect rheumatoid factor, antinuclear antibodies, and complement levels has been suggested as a method that can be used to confirm a diagnosis of RA or other connective tissue diseases. In particular, RA synovial fluids may be positive for rheumatoid factor, even when serum is not,²⁷ and complement levels are typically low as a result of consumption by immune

complexes. These findings are of insufficient sensitivity and specificity to be of value on a routine clinical basis.

Synovial Fluid Analysis in Arthritis Research

The ease with which synovial fluid is aspirated from effused joints has allowed a wide spectrum of research studies to be conducted on this biologic material. In research settings, cells in synovial fluid samples are typically separated by centrifugation, and cellular and noncellular components of the fluid are analyzed separately. Detailed analysis of the phenotype and functional properties of synovial fluid leukocytes has been particularly informative in RA and reactive arthritis research, where immunophenotyping of lymphocyte subpopulations has provided important clues to the pathogenesis of these diseases. In the case of reactive arthritis, in which triggering organisms are often identified, the proliferative and cytokine responses of synovial fluid lymphocytes to antigens derived from *Chlamydia*, *Yersinia*, and other pathogens have been elucidated.^{28,29} It has generally been shown that synovial fluid T cells from reactive arthritis patients are biased toward production of T helper (Th)2 cytokines such as interleukin (IL)-10 and IL-4, whereas synovial fluid T cells from RA patients are Th1 biased and exhibit defects in Th2 differentiation.³⁰⁻³²

Analysis of the noncellular portion of synovial fluid has provided important information regarding a spectrum of soluble molecules, including cytokines and growth factors,³³ extracellular matrix proteins, autoantibodies, and therapeutic drug levels. Moreover, broad-based proteomic studies of synovial fluid using fractionation techniques and mass spectrometry are beginning to provide novel approaches to understanding pathogenesis and prognosis in arthropathies such as RA.³⁴

SYNOVIAL BIOPSY

Sampling of synovial tissue is a direct approach to defining the pathologic processes that cause joints to be swollen and painful. In clinical settings, it can be particularly valuable in evaluating an undiagnosed persistent monoarthritis when other investigations, including synovial fluid analysis, have failed to provide a specific diagnosis. In research settings, analysis of synovial tissue samples has dramatically improved our understanding of the pathogenetic mechanisms underlying RA, spondyloarthropathies, and other chronic articular disorders. More recently, synovial biopsy has been explored as a method for defining the target tissue response to therapeutic agents, particularly targeted biologic therapies.

Blind Percutaneous Synovial Biopsy

Percutaneous needle biopsy is most commonly performed according to the method originally described by Parker and Pearson,^{35,36} utilizing a biopsy needle that now carries their name. Percutaneous synovial biopsy is most often performed on the knee joint, although the technique can readily be adapted for use in other joints such as wrist, elbow, ankle, or shoulder. A modification of the original Parker-Pearson needle has facilitated synovial biopsy of small hand joints such as metacarpophalangeal and proximal interphalangeal joints.³⁷ The technique for Parker-Pearson synovial biopsy

uses a 14-gauge needle with a lateral aperture just proximal to the inserted end of the needle. This lateral opening features a sharp cutting edge for severing trapped synovial tissue that is captured by applying suction with a 3- to 5-mL syringe. With this approach, multiple 1- to 3-mm samples are obtained by angling the trocar in several directions. This also serves to minimize the sampling error involved. Synovial samples are typically pink and are easily removed with a slight twisting motion. Because of the blind nature of the procedure, samples of fat, muscle, or fibrous tissue may be obtained and need to be separated from true synovial samples.

Percutaneous synovial biopsy is easily performed in most ambulatory care settings with the use of relatively inexpensive equipment. The overall morbidity of the procedure is low and is comparable with that of arthrocentesis, with perhaps a slightly higher rate of hemarthrosis, which can be minimized if the patient does not bear weight for a few hours after the procedure. The main disadvantage of the procedure is its blind nature. In comparison with visually guided arthroscopy, samples derived from the interface between synovium and adjacent cartilage are under-represented when the blind procedure is used.^{38,39} As is discussed later, this drawback is particularly relevant to a number of research questions.

Arthroscopically Guided Synovial Biopsy

Arthroscopy is widely used by orthopedic specialists for the diagnosis and treatment of a variety of articular disorders, particularly mechanical derangements of intra-articular structures such as cruciate ligaments and menisci. Over the past two decades, the arthroscopic procedure has been adapted for acquiring diagnostic synovial biopsies in settings that do not require a fully equipped operating theater and general anesthetic. In most cases, intra-articular local anesthesia suffices for the procedure, although conscious sedation may be required in some individuals. The procedure is well tolerated and is associated with low morbidity, although the risks of hemarthrosis and infection after the procedure are slightly higher than that of percutaneous needle biopsy. The patient should be instructed to minimize weight bearing for 24 to 48 hours after the procedure.

The primary advantage of arthroscopy is its ability to visually guide the biopsy procedure. This permits macroscopic evaluation of the synovium and sampling of areas that appear to be particularly severely affected by the pathologic process, and it allows for sampling of the interface between inflamed synovium and adjacent cartilage, this being an area of particular interest for understanding the pathogenesis of destructive arthropathies such as RA.³⁸ As with samples obtained by percutaneous synovial biopsy, individual samples are allocated for specific laboratory studies depending on the clinical or research question being addressed.

Processing Synovial Tissue Samples

In all cases, an adequate number of individual synovial specimens need to be allocated for routine light microscopy with the use of formalin fixation and paraffin embedding. This provides the highest-quality sections for hematoxylin

and eosin (H&E) histologic analysis, and it allows the most accurate delineation of pathologic processes within tissue. Although formalin-fixed sections can be used in some cases for immunohistology, formalin fixation alters the conformation of many protein antigens, making them inaccessible for specific identification by immunohistology. Many of the molecular markers used to analyze diseased synovium, including cell surface markers, cytokines, adhesion molecules, and proteases, require that tissue samples are snap frozen in a suitable mounting medium such as optimal cutting temperature compound, and then are sectioned with the use of a cryostat. The sections can be processed using antigen-specific monoclonal or polyclonal antibodies and color development achieved by one of several available immunofluorescence or immunoperoxidase methods. Typically, a nuclear counterstain is also used to assist in orientation of the tissue—hematoxylin in the case of immunoperoxidase studies. If only formalin-fixed, paraffin-embedded tissue is available, an alternative method for detecting antigens that are sensitive to formalin fixation is antigen retrieval.

Several antigen retrieval methods are available, including enzymatic and thermal methods,⁴⁰ which have been used to successfully retrieve a spectrum of antigens from archival synovial tissue samples for immunohistologic studies, although the quality of the tissue sections often deteriorates after antigen retrieval. A number of double-staining immunohistology techniques have been developed for simultaneous evaluation of the expression of two markers in the same tissue section, although these techniques are labor intensive and often require considerable experimentation to generate good stains.⁴¹ It should be noted that formalin fixation dissolves crystals, and if this is a diagnostic consideration, the specimen should be fixed in ethanol.

The sensitivity and specificity of molecular DNA and RNA techniques provide unprecedented opportunities for exploring the pathogenesis of synovial disorders. Although these studies can be carried out on very small quantities of tissue, great care needs to be taken in handling and processing tissue samples to prevent degradation of the nucleic acids, particularly in the case of RNA when RNAase enzymes are ubiquitous and can rapidly degrade the small quantity of RNA present in a tissue sample. As is discussed later, the search for microbial DNA and RNA has been of particular interest in attempts to understand the cause and pathogenesis of reactive arthritis, rheumatoid arthritis, and other forms of chronic synovitis of unknown cause. Techniques used to analyze human gene expression in small tissue samples have been rapidly improved. This has enabled the detection and quantitation of multiple mRNA transcripts in very small quantities of biopsy material, in many cases without the need for amplification.^{42,43}

SYNOVIAL PATHOLOGY

Synovial Membrane in Health

A detailed description of the composition of normal synovium is provided in Chapter 2. Histologically, the normal synovial lining layer is one to three cells thick and is composed of closely associated macrophage-like (type A) and fibroblast-like synoviocytes (type B) that are

Figure 53-6 Normal synovium. **A**, A lining layer one to two cells deep that is composed of macrophage-like synoviocytes (type A) and fibroblast-like synoviocytes (type B). **B**, Normal synovium stained for the enzyme uridine diphosphoglucose dehydrogenase, an indicator of hyaluronan synthesis by fibroblast-like synoviocytes.

not separated from the underlying stroma by a basement membrane, as is the case with a true epithelium. In many areas, visible gaps in this lining layer allow small molecules to easily diffuse through the extracellular matrix into the synovial fluid. The two types of lining layer synoviocytes are distinct and can be differentiated on the basis of ultrastructural and immunohistologic features. Macrophage-like synoviocytes are myeloid in origin, as they exhibit the morphologic characteristics of phagocytic cells and express macrophage markers such as CD68, CD14, and FcγRIIIa. Fibroblast-like synoviocytes are synthetic cells of mesenchymal origin that are the primary source of hyaluronan and other proteoglycans found in normal synovial fluid. They express CD55 (decay-accelerating factor [DAF]), high levels of vascular cell adhesion molecule (VCAM)-1, and the enzyme uridine diphosphoglucose dehydrogenase (UDPGD), which is involved in the synthesis of hyaluronan and has been detected by cytochemical methods (Figure 53-6). Fibroblast-like synoviocytes have also been shown to uniquely express cadherin-11, a specialized adhesion molecule that is involved in homotypic aggregation of these cells and that contributes to maintaining the integrity of the synovial lining layer.⁴⁴ Quantitatively, most of the cells in the normal synovial lining layer are synthetic type B cells. The underlying stroma features a rich network of capillaries with fenestrated endothelium in the immediate sublining area that serve to maintain the health and viability of adjacent cartilage. Larger arterioles and venules can be found deeper in the synovial stroma. The synovial microvasculature is surrounded by loose connective tissue, which also incorporates the synovial lymphatics that serve to drain this tissue. It has been shown that the synovium of completely asymptomatic individuals not uncommonly exhibits a modest infiltrate of T lymphocytes that are occasionally organized in perivascular aggregates, although B cells were not seen.⁴⁵

Synovial Histopathology in the Evaluation of Monoarthritis

Pathologic analysis of synovial tissue samples can be of considerable value in certain clinical settings. Having said this, it should be kept in mind that the histopathologic interpretation of synovial biopsy specimens is often nondiagnostic and lacking in specificity.⁴⁶ Pathologic analysis of

synovial samples from patients with undiagnosed monoarthritis may be of particular value. The presence of large numbers of neutrophils in the synovial tissue stroma is highly suggestive of septic arthritis, and in such cases Gram stain may reveal bacteria in the tissue. Because septic arthritis is usually acute in onset, synovial biopsy is rarely required, and the diagnosis can be made by analyzing synovial fluid as described previously. Gonococcal arthritis may require synovial biopsy for diagnosis (Figure 53-7). A mononuclear cell infiltrate, on the other hand, is more consistent with a chronic inflammatory process and has a wide differential diagnosis, as has been described. The presence of granulomas supports a diagnosis of tuberculous arthritis or sarcoidosis, both of which cause chronic monoarthritis. The synovial granulomas of tuberculosis (TB) may be caseating or non-caseating, and staining of the tissue for acid-fast bacilli, culture, and molecular probing can yield a definitive diagnosis in an estimated 50% of cases. Similarly, a spectrum of fungal infections can be diagnosed using similar approaches, but special stains such as Gomori may be required. The diagnosis of sarcoid arthropathy is suspected in synovial specimens with noncaseating granulomas in cases where mycobacterial or fungal infection has been excluded.

Pigmented villonodular synovitis is an important consideration in individuals with chronic monoarthritis of a large joint such as the knee or hip. This disorder has a characteristic magnetic resonance imaging (MRI) appearance caused by hemosiderin deposits in the synovium and large cystic lesions in adjacent bone. Histopathologic analysis of the synovium can confirm this diagnosis and demonstrates a diffusely hypervascular proliferative lesion with mononuclear cells of the monocyte/macrophage lineage, foamy multinucleated cells resembling osteoclasts, and hemosiderin deposits⁴⁷ (see Figure 53-7). Synovial sarcomas are rare tumors that must be diagnosed on the basis of synovial pathology.

Synovial Histopathology in the Evaluation of Polyarthritis

In current clinical practice, the availability of well-validated diagnostic criteria and specific serologic tests, combined with a relative lack of specificity in synovial histopathologic features, limits the clinical utility of synovial pathology in the differential diagnosis of oligoarthritis and polyarthritis. On

Figure 53-7 **A**, Synovial pathology of gonococcal arthritis. the other hand, analysis of synovial tissue samples obtained in the context of research studies from patients with RA and various spondyloarthropathies has dramatically enhanced our understanding of the cellular and molecular mechanisms of these disorders. This is reflected in a large body of literature published over the past three decades.^{38,48}

RA synovium has been the most extensively studied histopathologically, and a detailed discussion of RA synovitis can be found in Chapter 69. The two characteristic features seen in RA synovitis are hyperplasia of the lining layer and infiltration of the sublining stroma with mononuclear cells (Figure 53-8). The surface of the lining layer

Figure 53-8 Histopathology of rheumatoid arthritis synovitis. **A**, Lymphoid aggregate. **B**, Diffuse lymphocytic infiltrate. **C**, Hyperplasia of the lining layer. **D**, Fibrin cap replacing a denuded lining layer.

is often covered with fibrin deposits generated from activation of the fibrinolytic system in inflammatory synovial fluid. Occasionally the synovial lining layer is completely denuded and is replaced by a dense fibrin cap. In highly inflamed tissues, fibrin deposits extend deeply into the sublining stroma, which may be edematous owing to the marked increase in vascular permeability. The earliest synovial changes in RA appear to feature microvascular abnormalities,⁴⁹ and mononuclear cell infiltrates have been detected in asymptomatic joints of RA patients.^{50,51} These features are nonspecific and are seen in the synovium of acutely inflamed joints from a spectrum of disorders, including reactive arthritis and psoriatic arthritis.

In RA, the mononuclear cell infiltrate in the sublining stroma can be diffuse but more commonly is arranged in perivascular aggregates resembling lymphoid follicles (see Figure 53-8). Although the presence of lymphoid aggregates in the synovial membrane is typical of RA, this histopathologic feature is by no means unique to RA synovitis.⁵²⁻⁵⁵ Lymphoid follicles are typically located near vessels with tall endothelium, which are termed *high endothelial venules*; these vessels specialize in the recruitment of lymphocytes (Figure 53-9). Multinucleated giant cells are occasionally seen in RA synovium (Figure 53-10), and some tissues demonstrate granuloma formation. Finally, it should be noted that synovial tissue obtained at the time of joint arthroplasty often exhibits extensive fibrosis and may be indistinguishable from arthroplasty samples obtained from patients with osteoarthritis.

The synovial histopathology of psoriatic arthritis, ankylosing spondylitis, and reactive arthritis has been compared with that of RA.^{56,57} In all cases, a similar spectrum of inflammatory cell populations has been identified, but several subtle and potentially important differences have been observed. Overall, synovial histologic and immunohistologic features of psoriatic arthritis, both oligo- and polyarticular, resemble those of other spondyloarthropathies to a greater extent than RA (see later under “[Synovial Immunohistology](#)”).⁵⁷ Comparative studies have suggested that synovial lesions in psoriatic arthritis are more vascular than those of RA, with more tortuosity of the synovial

Figure 53-9 Microarchitecture of rheumatoid arthritis synovial lymphoid aggregates.

Figure 53-10 Multinucleated giant cell in a patient with rheumatoid arthritis.

microvasculature.^{58,59} This is evident both macroscopically and microscopically. Moreover, lymphoid aggregates of various sizes were identified in 25 of 27 synovial tissue samples from patients with psoriatic arthritis, and 13 of 27 had large organized aggregates with all of the features of ectopic lymphoid neogenesis that have been associated with RA synovitis.⁵² Studies of synovium from the peripheral joints of ankylosing spondylitis patients have revealed intense infiltrates of lymphocytes, plasma cells, and lymphocytic aggregates.^{60,61} Comparisons made between the synovial lesions seen in reactive arthritis (ReA) and those seen in early RA of similar disease duration suggest that ReA synovia are less infiltrated with B lymphocytes, plasma cells, and macrophages.^{62,63} It should also be noted that synovium from patients with osteoarthritis often features the presence of lymphocyte aggregates, although these tend to be small and less well developed than those seen in RA.⁵⁴

The synovium of lupus patients showed synovial hyperplasia, inflammatory infiltrates, vascular proliferation, edema and congestion, fibrinoid necrosis and intimal fibrous hyperplasia of blood vessels, and superficial fibrin deposits, although these changes were quantitatively modest compared with those of RA.⁶⁴ In early scleroderma, the lining layer was seen to be thin with deposits of fibrin and stromal lymphocytes and plasma cells,⁶⁵ and similar changes were seen in patients with dermatomyositis and polymyositis⁶⁶ (see Figure 53-7). A recent study comparing the immunopathologic features of early untreated Behçet's disease versus those of psoriatic arthritis (PsA) noted that although a similar degree of inflammation was seen in the two disorders, Behçet's synovitis demonstrated higher numbers of neutrophils and T cells than were seen in psoriatic synovitis.⁶⁷

In patients with chronic crystal arthropathies, large deposits of birefringent material can be detected in the synovium.⁶⁸ Amyloid arthropathy can be diagnosed by demonstrating amyloid deposits in the synovium using Congo red staining (see Figure 53-7). The synovium in ochronosis contains brownish shards of cartilage.⁶⁹ Multicentric reticulohistiocytosis can be diagnosed pathologically by the presence of large foamy cells and multinucleated cells in the synovium. In arthritis of hemochromatosis, the synovium

exhibits brown hemosiderin deposits in the lining cells, and CPPD crystals can also be observed.⁷⁰

SYNOVIAL IMMUNOHISTOLOGY

Considerations Regarding Sampling and Quantitative Analysis

Immunohistology utilizes specific monoclonal or polyclonal antibodies with well-defined molecular targets and is an effective tool for analyzing the cellular and molecular features of the synovium. As the field has progressed over the past two decades, it has become clear that algorithms for generating reproducible quantitative data from immunohistologically stained sections are required. Moreover, approaches are needed for minimizing the sampling bias that is inherent in biopsy-based studies.⁷¹ Studies have suggested that if six or more individual specimens from different parts of the joint are examined, variance is reduced to less than 10% for T cell and activation markers.⁷² Furthermore, it has been shown that synovial inflammatory features are similar in areas adjacent to and distant from the pannus cartilage junction, with the possible exception of macrophage numbers, which tend to be higher in adjacent areas.^{73,74}

Various methods have been proposed by which quantitative data for immunohistologically stained synovial tissue sections can be generated.^{75,76} The easiest and least costly method is to generate semiquantitative scores of staining intensity (e.g., on a 0 to 3 scale) from multiple areas of the tissue, and on the basis of these to obtain an average score for the entire tissue. The reliability and reproducibility of this method are increased if two observers score the tissue sections independently and a final average of the scores is

generated. Computer-assisted image analysis involves capturing images from multiple areas of the tissue samples to which color-specific quantitative software algorithms are then applied. This method generates the greatest quantity of reproducible data but requires expensive equipment and certain levels of operator skill. Furthermore, differences in the background staining intensity of individual sections can make this type of analysis technically difficult.

Synovial Lining Cell Layer

Compared with normal synovium, the lining layer in RA is often hyperplastic, resulting from an increase in both type A and type B cells, as indicated by an increase in CD68 and CD55 staining, respectively (Figure 53-11). It is assumed that macrophage-like synoviocytes are recruited from the blood and then migrate through the synovial stroma and ultimately are retained in the lining layer in close association with fibroblast-like synoviocytes. It is currently proposed that the increase in fibroblast-like synoviocytes may be related more to defects in apoptosis than to recruitment or local proliferation. Expression of several families of adhesion molecules by both types of lining cells results in their close association and modulates their activation status. These include $\beta 1$ and $\beta 2$ integrins and their respective immunoglobulin supergene family ligands, particularly intercellular adhesion molecule (ICAM)-1 and VCAM-1.⁷⁷⁻⁷⁹ Cadherin-11 expressed by fibroblast-like cells likely plays a key role in the adhesive interactions that sustain the lining layer hyperplasia.⁴⁴ This adhesion molecule is widely expressed in the lining layer of normal cells, as is shown in Figure 53-12. The relationship between fibroblast-like synoviocytes in the lining layer and other populations of

Figure 53-11 A-D, Immunoperoxidase staining of normal synovium and rheumatoid arthritis (RA) synovium for CD55 (fibroblast-like synoviocytes) and CD68 (macrophage-like synoviocytes). Both subsets of lining cells are increased in the hyperplastic lining layer of RA synovium.

Figure 53-12 Expression of cadherin-11 in the normal synovial lining layer (**B**). Control staining is shown in **A**. (Adapted from Lee DM, Kiener HP, Agarwal SK, et al: Cadherin-11 in synovial lining formation and pathology in arthritis, *Science* 315:1006–1010, 2007.)

mesenchymal cells in the sublining stroma remains uncertain. Immunohistology indicates that expression of CD55, VCAM-1, and cadherin-11 is primarily seen in the lining cell layer with minimal evidence of expression in sublining fibroblast populations. Similarly, our understanding of the relationship between lining layer macrophage-like cells and sublining macrophages is incomplete, and both express widely used macrophage markers such as CD68 and CD14. Seminal work from Edwards and associates has suggested that macrophage-like lining cells preferentially express Fc γ RIIIa receptors, which may serve to localize immune complexes to the synovium.⁸⁰

Functionally, the lining cell layer in RA is highly activated. Human leukocyte antigen (HLA)-DR is highly expressed, particularly by macrophage-like cells, which may suggest a role for these cells in antigen presentation.⁸¹ Several studies have indicated that cells in the RA lining layer are the principal source of cartilage-degrading proteases, particularly matrix metalloproteinase (MMP)-1 and MMP-3^{82,83} (Figure 53-13). The lining layer is generally less hyperplastic in spondyloarthropathies such as PsA and reactive arthritis compared with RA.^{57,61,84} Less is known about the functional state of the lining cells in these disorders, although it is likely that differences compared with RA are quantitative rather than qualitative.

Synovial Lymphocytes and Plasma Cells

In the synovial tissues of RA and spondyloarthropathies patients is a predominance of CD3⁺ T cells, and the CD4/CD8 ratio is 4:1 or greater in the lymphocytic aggregates but is lower in more diffuse infiltrates. Moreover, the CD4

cells in the aggregates also express CD27,⁸⁵ which facilitates B cell help. Considerable attention has been paid to whether the infiltrating T cells in RA and other arthropathies are primarily Th1 (interferon [IFN]- γ producing) or Th2 (IL-4 producing) biased, but the data in this area have been inconsistent. Until recently, it was suggested that T cells in RA synovium are more Th1 biased compared with those in synovium from spondylarthropathies, with a higher Th1/Th2 cytokine ratio.⁸⁶ Identification of a third subset of T helper cells expressing IL-17 and playing a central role in chronic inflammatory disorders has necessitated a revision in the role that T cells play in synovitis.^{87,88} The presence of IL-17, IL-1 β , and tumor necrosis factor (TNF) in RA synovium was found to be predictive of progressive damage.⁸⁹ Furthermore, a subset of CD4 T cells expressing CD25 and the gene *FoxP3*, so called regulatory T cells (Tregs), are now known to play a regulatory role in antigen-specific T cell expansion. Although Tregs are readily detected in the joints of patients with RA and other inflammatory arthropathies, their suppressor function appears to be defective in this microenvironment.⁹⁰⁻⁹³ It has been suggested that CD8 T cells are needed to maintain the structure of ectopic lymphoid-like structures in RA synovium, even though the numbers of these T cells typically are substantially lower than the numbers of CD4⁺ cells.⁹⁴

B cells are identified by expression of CD19 and CD20 and are particularly abundant in tissues exhibiting large lymphoid aggregates with germinal centers. B cells typically are found in close association with CD4-positive T cells in these aggregates (see Figure 53-9). Experiments in severe combined immunodeficiency (SCID) mice suggest that B cells may be critical for maintaining the microarchitecture of synovial lymphoid follicles and for T cell activation.⁹⁵ Memory B cells are efficient antigen-presenting cells, and rheumatoid factor-producing B cells are well suited for capturing a wide spectrum of antigens in immune complexes.

In RA synovium in particular, areas surrounding the lymphoid aggregates are often densely infiltrated with sheets of CD38⁺ plasma cells. Analysis of V gene variants and rearrangements in B cells and plasma cells in RA and reactive arthritis synovium indicates that plasma cells from a particular aggregate are clonally related, suggesting that their terminal differentiation occurred in the synovial microenvironment.⁹⁶ Synovial plasma cells actively synthesize immunoglobulin, some of which has been shown to result in the production of autoantibodies such as anti-citrulline antibodies, which recognize local citrullinated antigens.⁹⁷⁻⁹⁹ As has been stated, plasma cell infiltrates are also seen in PsA, ankylosing spondylitis, and reactive arthritis synovium, although a systematic analysis of synovial samples from patients with early arthritis has suggested that their presence is most suggestive of RA.⁶² It was found in one study that intracellular citrullinated proteins were detected in RA but not in spondylarthropathy synovium.⁵⁷ In contrast, another study found that the presence of citrullinated proteins was not specific for RA synovitis.¹⁰⁰

The areas immediately adjacent to the dense lymphoid aggregates, which comprise primarily CD4⁺ T cells and B cells, have been called *transitional zones*^{101,102} (see Figure 53-9). These areas feature a lower CD4/CD8 ratio and appear to be particularly active immunologically.

Transitional areas are rich in macrophages and interdigitating dendritic cells, both of which are highly efficient antigen-presenting cells. Lymphoblasts, in particular CD8⁺ T cells, are seen to be present in close proximity to antigen-presenting cells.

Natural killer cells can be identified by cell surface markers, expression of granzymes, and functional assays. Several studies have suggested an expansion of subsets of natural killer cells in RA synovial tissue and synovial fluids.¹⁰³⁻¹⁰⁵ Mast cells are abundant in RA synovium and co-localize with inflammatory mediators and proteases in the synovial microenvironment.^{106,107}

Synovial Sublining Macrophages and Dendritic Cells

Macrophages are present in the sublining areas of healthy and diseased synovium but are particularly abundant in the sublining stroma of RA synovium. Indeed, when markers such as CD68 and CD14 are used to study highly inflamed tissues, no clear distinction can be made between the sublining macrophage population and the macrophage-like synoviocytes present in the hyperplastic lining layer, although expression of complement receptor for C3b and iC3b was shown to be unique for lining macrophages in RA, osteoarthritis, and normal synovium.¹⁰⁸ Studies using various macrophage markers suggest that recently migrated macrophages in perivascular areas express CD163 brightly, in addition to expressing CD68 and CD14, whereas macrophages in large lymphocytic aggregates and in the lining layer are less likely to express CD163. CD163⁺ macrophages, which have recently been called M2 macrophages, were found to be more abundant in spondylarthropathy than in RA synovium.⁵⁷ The functional correlates of these phenotypic differences remain unclear.¹⁰⁹⁻¹¹¹ M1 macrophages, which produce TNF and IL-1 β , are more abundant in RA and are under-represented in PsA and other spondylarthropathies in which M2 macrophages are more abundant.¹¹¹ Furthermore, it has been shown that the number of macrophages in RA synovium, primarily of the M1 subset, correlates well with the destructive potential of the synovitis, as evidenced by erosive radiographic damage.¹¹²⁻¹¹⁴ This may reflect the highly activated status of these cells, which serve as the principal source of synovial TNF and IL-1 β . A body of evidence has suggested that populations of synovial macrophages serve as osteoclast precursors that mature in the synovial microenvironment and then directly mediate erosive damage to adjacent bone.^{115,116}

Mature dendritic cells are the most efficient and potent of the antigen-presenting cells, and are found abundantly in RA synovium in close contact with T lymphocytes.^{117,118} Two major subsets of dendritic cells have been described: myeloid dendritic cells (mDCs) and plasmacytoid dendritic cells (pDCs). They can be identified by immunohistology as stellate cells with dendrites expressing high levels of HLA-DR and co-stimulatory molecules such as CD80, CD83, and CD86. mDCs express CD11c and CD1c, and pDCs express CD304.¹¹⁹ One study suggested that compared with psoriatic synovitis, the RA synovium is particularly enriched in pDCs.¹¹⁹ Detailed studies that have examined the expression of chemokines involved in dendritic cell

migration and recruitment suggest that a substantial proportion of dendritic cells in the synovium arrive in an immature state and subsequently undergo maturation within the synovial microenvironment in a T cell-rich area.^{117,118} Follicular dendritic cells in the germinal centers of large lymphocytic aggregates express the markers CD16, FDC, and VCAM-1.

Synovial Microvasculature, Endothelium, and Stromal Mesenchymal Cells

The stromal elements in RA are often expanded in parallel with the inflammatory cell infiltration. The microvasculature appears to be markedly increased, particularly in the deep sublining areas, and this expansion is presumed to relate to local stimulation of angiogenesis (see Figure 53-13). Morphometric studies have suggested that the number of vessels immediately adjacent to the lining layer is actually reduced compared with normal.¹²⁰ This situation, combined with the metabolic demands of this tissue, may actually produce a relatively ischemic and hypoxic environment, which is reflected in the biochemical properties of RA synovial fluid.¹²¹ Immunohistologic studies have indicated that the molecular consequences of hypoxia, particularly expression of hypoxia-inducible factor-1 α (HIF-1 α), a key regulator of the cellular hypoxic response, are increased in RA synovitis.^{122,123} Studies that have directly measured synovial tissue pO₂ using arthroscopic probes have confirmed the hypoxic nature of RA synovitis.¹²⁴⁻¹²⁶ The synovial endothelium in RA and other inflammatory arthropathies is activated by proinflammatory mediators in the microenvironment to express adhesion molecules such as E-selectin, ICAM-1, and VCAM-1, which are involved in the recruitment of inflammatory cells.¹²⁷

Synovial-Cartilage-Bone Interface

The interface between inflamed synovium and adjacent cartilage and bone in RA and other chronic arthropathies is a site of particular interest because much of the articular damage occurs in these areas. In RA, this destructive synovial tissue is called *pannus*, which may spread to cover most of the surface of the cartilage and invade the bone in bare areas at the joint margin (Figure 53-14). Pannus has been pathologically characterized primarily from samples obtained

at the time of joint arthroplasty, although arthroscopic studies at earlier stages of disease have attempted to characterize synovial samples adjacent to this area. Immunohistology suggests that synovial macrophages and fibroblasts are abundant at the pannus-cartilage interface, and that high levels of proteases are expressed by these cells. At the interface between pannus and bone, substantial numbers of multinucleated osteoclasts can be identified morphologically and by specific markers such as calcitonin receptors, cathepsin K, and staining for tartrate-resistant acid phosphatase¹²⁸ (see Figure 53-14). Moreover, expression of receptor activator of nuclear factor κ B (NF κ B) ligand (RANKL), a key cytokine in osteoclastogenesis, was prominent in these areas.¹²⁹

Synovial Biopsy and Pathology as Tools for Predicting and Assessing Response to Therapy in Inflammatory Arthritis

Numerous academic rheumatology centers have focused on using serial arthroscopic biopsy and quantitative immunohistology as tools to assess the impact of therapeutic interventions on synovial lesions in RA. These studies have been particularly valuable in evaluating the effects of targeted biologic therapies, where the molecular target and the biologic basis of the mechanism of action are well defined.¹³⁰⁻¹⁴¹ It has been proposed that synovial biopsy-based studies, which are relatively small and inexpensive to undertake, offer a unique opportunity to assess the impact of novel therapeutic agents on the target tissue at an early stage of pharmaceutical drug development. On the basis of these studies, it may be possible to make important decisions regarding the future development of a particular agent.

This appealing proposition is currently hindered by several important considerations. First, the arthroscopic equipment, expertise, and infrastructure needed to undertake these studies remain limited to a small number of centers. Second, considerable concern has arisen regarding the issue of sampling bias in these studies, particularly because serial biopsies are compared in the same individual. As has been discussed, various approaches are used to minimize this bias, including systematic sampling of the same areas of the joint, computerized image analysis of multiple representative tissue samples, quantification of an adequate number of microscopic fields, and utilization of quantitative

Figure 53-14 Interface between pannus tissue and bone in a patient with rheumatoid arthritis. **A**, The synovial lesion is invading adjacent bone. **B**, Staining for tartrate-resistant acid phosphatase in the circled area demonstrates the presence of osteoclasts.

PCR and proteomic techniques to assess overall levels of specific molecules. Finally, and most important, has been the lack of a synovial biomarker(s) with which to reproducibly evaluate outcomes across various studies. The number of macrophages in the tissue has been proposed as a good candidate biomarker, although this remains to be systematically tested.^{132,142}

SUMMARY

Analysis of synovial fluid and tissue samples provides valuable diagnostic information in specific clinical settings. In cases where septic or crystal-induced arthritis is suspected, as in acute monoarthritis, synovial fluid analysis is critical for making the diagnosis. In cases of undiagnosed chronic monoarthritis, synovial biopsy may provide definitive evidence of conditions such as tuberculosis, sarcoidosis, and pigmented villonodular synovitis.

Systematic analysis of synovial tissue in RA and other forms of inflammatory arthritis, particularly with the use of immunohistology, has provided a wealth of information concerning the cellular and molecular mechanisms that sustain synovial lesions. Research protocols are currently exploring the utility of synovial biopsy in predicting response to antirheumatic therapies.

KEY POINTS

Arthrocentesis with joint injection is a simple, low-risk, office-based procedure that can be extremely useful diagnostically and therapeutically.

Diagnostic arthrocentesis is indicated in patients with effusion without a known diagnosis or if a new diagnosis is suspected, and it can be definitive for infection- or crystal-induced disease.

Therapeutic corticosteroid injection can potentially provide clinical benefit for many painful joints or periarticular structure.

Most forms of noninfectious inflammatory arthritis respond to local injection.

Clinical trials of injection in osteoarthritis of the knee show benefit compared with placebo, but duration varies.

Evidence for efficacy of corticosteroid injection for nonarticular conditions is best for painful shoulders, but many other conditions have been shown to respond in small trials or anecdotal reports.

Arthrocentesis and injection of joints are safe and simple procedures that can be performed routinely at an outpatient visit.¹ With analysis of synovial fluid, few procedures in medical practice have the potential to be as diagnostically definitive as arthrocentesis and few modalities can be as effective in achieving symptomatic relief of painful or swollen articular structures as the injection of corticosteroids. For these reasons, one out of five visits to a rheumatology practice includes aspiration or injection of a joint or periarticular structure. However, a majority of internists finishing their residency training believe they need more training in these important, safe, and effective procedures, and most injections performed in primary care settings are done by a small percentage of practitioners with experience and comfort with the procedure. Recent efforts to formalize educational processes in arthrocentesis and joint injection have the potential to increase the number of primary care physicians who use these procedures more regularly.

Paracelsus is credited with the first descriptions, in the early sixteenth century, of the viscous fluid present within synovial cavities, but aspiration of synovial fluid for analysis and aid in diagnosis did not become a topic of increasing interest until the first half of the twentieth century. Numerous studies of synovial fluid components and techniques used to obtain this fluid appear in a 1935 textbook by Pemberton.² An early description of arthrocentesis technique can be found in the classic book by Ropes and Bauer³ on

Arthrocentesis and Injection of Joints and Soft Tissue

CHRISTOPHER M. WISE

synovial fluid analysis, published in 1953, which used data collected over a 20-year period. During this era, swollen, distended joints were often aspirated for relief of discomfort. In most instances, the prompt reaccumulation of fluid and concerns about infection from repeated aspirations limited the usefulness of aspiration for the relief of arthritis symptoms. A wide variety of substances were injected into joints throughout the early twentieth century including formalin and glycerin, ethiodized oil (Lipiodol), lactic acid, petroleum jelly, and liquefied oil prepared from the patient's own subcutaneous fat. Most of these therapies were apparently abandoned, and the most therapeutic injections discussed in arthritis textbooks from the 1940s related to temporary relief via injections of procaine for osteoarthritic knees and bursitis of the shoulder.

In 1951, after observations on the efficacy of topical cortisone for ocular inflammation, Hollander first reported a minimal, transient improvement in 25 knees of patients with rheumatoid arthritis when injected with cortisone. In subsequent years, Hollander injected hydrocortisone acetate with a much better response, providing further evidence that this was the active anti-inflammatory metabolite of cortisone.⁴ Further reports of benefit from injectable corticosteroids appeared in the 1950s. During this period, studies showed that more stable and less soluble compounds in the form of esterified crystalline hydroxycortisone and its analogues were even more effective and had longer duration of anti-inflammatory effects. By the early 1960s, Hollander had reported a series of more than 100,000 injections of joints, bursae, and tendon sheaths in 4000 patients with a variety of conditions. In rheumatology practice since then, aspiration and therapeutic injection of joints and periarticular tissues have become common and essential procedures.

INDICATIONS AND CLINICAL EVIDENCE

Arthrocentesis

Aspiration of synovial fluid may be indicated in any joint with detectable effusion or may be attempted in joints without detectable effusions when diagnosis is in doubt (Table 54-1).⁵ In patients in whom a diagnosis is uncertain, synovial fluid analysis usually provides important information regarding the inflammatory or noninflammatory nature of the process within the affected joint and may be definitive in patients with crystal-induced or infectious arthritis. In patients with recently diagnosed bacterial arthritis, repeated aspiration of accumulated fluid is often an important adjunct to antibiotic therapy. Joints with detectable effusions may be aspirated for relief of discomfort, with or without a subsequent injection of corticosteroid. In some

Table 54-1 Indications for Arthrocentesis

Undiagnosed Arthritis with Effusion
Characterize type of arthritis
Noninflammatory (WBC < 2000/mm ³)
Inflammatory (WBC > 2000/mm ³)
Septic (WBC > 50,000/mm ³)
Definitive diagnosis
Gout (urate crystals)
Pseudogout (calcium pyrophosphate dihydrate crystals)
Septic arthritis (Gram stain [rare] or culture)
Undiagnosed Arthritis without Effusion
May be definitive in gout (knee, first metatarsophalangeal joint)
Patient with Known Diagnosis
Septic arthritis (repeated taps for adequate drainage)
Other types of arthritis for symptomatic relief (with or without injection)*

*Most studies show improved effect if fluid aspirated before injection.
WBC, white blood cells.

patients, aspiration alone, without steroid injection, may be particularly effective for noninflammatory effusions or self-limited conditions.

THERAPEUTIC INJECTION

Inflammatory Arthritis

Therapeutic injection of corticosteroids is generally believed to be most effective in joints affected by inflammatory arthritis (Table 54-2). Most of the experience in this area has been with common conditions such as rheumatoid arthritis, juvenile rheumatoid arthritis, crystal-induced arthritis, psoriatic arthritis, and reactive arthritis. Anecdotal experience has been reported in less common conditions such as systemic lupus erythematosus and sarcoidosis. In self-limited conditions such as gout, injections generally lead to more prompt resolution of exacerbations.

In rheumatoid arthritis, injections are used frequently to suppress inflammation in individual joints. Such injections are generally considered to be adjunctive to disease-modifying drug therapy and are not believed to affect overall outcomes. The efficacy of individual joint injections in rheumatoid arthritis is supported by many large, uncontrolled case series dating back to the 1950s. Most of Hollander's early reports suggested long-lasting relief in most joints injected, with improvement lasting several months in most patients.⁶ This long-lasting relief has been confirmed in several series of patients in subsequent years. In 1972 McCarty⁷ reported that 88% of patients attained remission for an average of 22 months in small joints of the hands and wrists, much better than comparable joints not injected in the opposite hands of the same patients. In a subsequent report on 956 injections in 140 patients followed for an average of 7 years, 75% of injected joints remained in remission.⁸ In this series, patients received about two injections during the first year of treatment and averaged 0.6 injection per patient-year for the next 15 years.

More recently, multiple intra-articular injections in inflamed joints have been shown to be a useful part of an overall regimen of disease-modifying therapy in rheumatoid arthritis, resulting in improvement superior to similar doses of systemic steroids, and helpful in obtaining

clinical remission and reducing radiographic progression of disease.⁹⁻¹¹ In particular, intra-articular injections of steroids added to systemic methotrexate therapy have been shown to improve periarticular osteopenia in swollen hand joints over a 3-month period in patients with rheumatoid arthritis.¹² Removal of fluid before aspiration increases the efficacy of steroid injections in most patients with inflammatory arthritis. One study of 191 knee injections in patients with rheumatoid arthritis showed that aspiration of fluid reduced the rate of relapse from 47% to 23% within a 6-month period after injection compared with joints not aspirated.¹³

Corticosteroid injection is considered to be a safe and effective option for prompt relief of acute crystal-induced

Table 54-2 Indications for Therapeutic Injection

Inflammatory Arthritis
Rheumatoid arthritis: almost always effective; duration varies; should be used as an adjunct to an overall regimen of disease-modifying therapy, efficacy equivalent to or superior to systemic steroids
Crystal-induced arthritis: few published studies; effective in 24-48 hr
Undiagnosed early inflammatory oligoarthritis: complete response in 2 wk in 57%; predictor of good outcome
Spondyloarthropathies
Peripheral joints respond as in rheumatoid arthritis
Sacroiliac joint injections under imaging guidance
Juvenile rheumatoid arthritis: particularly useful in oligoarticular form; may be "disease modifying" and safer than nonsteroidal anti-inflammatory drugs
Miscellaneous diseases (anecdotal)
Sarcoidosis
Systemic lupus erythematosus
Noninflammatory Arthritis
Osteoarthritis
Knees: 60%-80% response in 1-6 wk versus placebo; no difference at 12 wk, global improvement over 2 years with every 3-month strategy but no lasting effect
Hips: anecdotal reports; require fluoroscopy; usually avoided
Hyaluronic acid derivatives (Hyalgan, Synvisc) weekly for 31-35 wk: moderately better than placebo
Hemophilic arthropathy: reported, but rarely used
Nonarticular Conditions (Tendinitis, Bursitis, Myofascial Pain)
Trigger point injections: done frequently; not supported by studies
Painful shoulder (rotator cuff tendinitis, frozen shoulder): efficacy compared with placebo; lasting 4-6 mo
Lateral epicondylitis (tennis elbow): efficacy for 1-2 mo versus placebo; less in some studies, possible increased recurrences later
Carpal tunnel syndrome: 90% short-term response; variable at 6-12 mo; good response to injection may be predictor of surgical response
de Quervain's tenosynovitis: 70%-90% improved with 1-2 injections, relapse in 30% at 1 yr
Trochanteric pain of hip (bursitis, tendinitis): 60%-70% at 6 mo (uncontrolled)
Knee pain syndromes
Anserine bursitis
Patellofemoral pain syndromes
Synovial plica
Popliteal cyst (usually treated with intra-articular knee injection)
Plantar fasciitis: variable; probably better for 1-3 mo
Morton's neuroma: response often prolonged (no controls)
Tarsal tunnel syndrome: rarely reported; usually only temporary
Achilles tendinitis, bursitis: usually avoided
Cervical girdle, lumbar areas, posterior hip: uncertain what structure injected (without fluoroscopic facet block); efficacy not proved

arthritis in gout and pseudogout. Steroid injections are so widely accepted as an effective treatment that few reports have attempted to address the degree or duration of efficacy for injections in these conditions. Many of the patients described in early reports of steroid injections were being treated for acute crystal-induced arthritis, with prompt relief being almost uniform. In a more recent report, small doses of intra-articular steroids were successful in relieving pain and swelling completely in all patients within 48 hours, and no relapses were noted in 20 patients over a 3-month period.¹⁴

In patients with recent onset of inflammatory oligoarthritis, without definitive diagnosis, corticosteroids can be used to relieve symptoms of swelling in individual joints, and the response to these injections can be used as a prognostic marker. In a series of 51 patients with recent-onset inflammatory arthritis involving five or fewer joints, a strategy of injecting all joints with clinical synovitis resulted in improvement in all patients and a complete resolution of synovitis after 2 weeks in 57% of patients. The response at 2 weeks was the best predictor of continued improvement persisting for 26 weeks and 52 weeks.¹⁵ A trial of steroid injection may be used for symptomatic relief in such patients, and a complete response at 2 weeks can be used as a prognostic indicator for a better outcome. Local injections are effective in 41% and 25% of joints at 3 and 12 months, respectively, in patients with localized flares of psoriatic arthritis, with the response more prolonged in patients taking effective long-acting systemic therapy.¹⁶

Patients with refractory sacroiliac joint pain related to ankylosing spondylitis or other spondyloarthropathies may benefit from injection of the sacroiliac joints.¹⁷ Because of the anatomy of this joint, such injections often require radiographic confirmation of needle placement in the joint space, and use of fluoroscopy-guided, computed tomography (CT)-guided, and magnetic resonance imaging (MRI)-guided injections has been reported. In uncontrolled studies, a good response has been reported in about 80% of injections, with an average time of improvement of 6 to 9 months. At least one controlled study in a small group of patients showed slight benefit of steroid compared with placebo injection. The degree of improvement seen after sacroiliac injections has not been consistent among studies to date, however, probably because of a lack of uniformity of patient selection and outcomes assessed.

Joint injection has been used with increasing frequency in recent years in patients with juvenile rheumatoid arthritis,¹⁸ particularly in the pauciarticular variant of the disease, in which only a few joints are involved, and potentially toxic systemic therapy can be avoided. Complete remission lasting more than 6 months has been reported in approximately 65% to 80% of joints injected in this condition, most commonly in the knees. Benefit has also been shown in smaller numbers of ankles, wrists, shoulders, elbows, and temporomandibular joints, with most children being able to stop oral medications, and correction of joint contracture being noted in most as well.¹⁹ A median duration of improvement of approximately 74 weeks has been documented in another large study. Joint lavage before injection may be useful in prolonging response in patients with a poor response to previous injection.²⁰ One study showed a significant decrease in leg-length discrepancy in

children treated with repeated injections (average of 3.25 injections per child over 42 months) compared with children in another center who were not injected.²¹ A recent decision analysis model suggests that intra-articular injection is superior to a strategy of initial nonsteroidal anti-inflammatory (NSAID) use in patients with monoarthritis of the knee.²²

A more recent study specifically addressed the efficacy and safety of steroid injections in the hip in juvenile rheumatoid arthritis.²³ In this prospective study of 67 hip injections, 58% of hips remained in remission for 2 years after a single injection; another 18% required a second injection to maintain remission. Only two cases of avascular necrosis were seen in this group, and both of these were in patients receiving systemic steroids, suggesting no role for local steroid injections in the development of avascular necrosis in this population.

Finally, local steroid injection may be a useful adjunct in managing patients with hemophilic arthropathy.²⁴ In an open trial of 19 injections, 79% of joints improved within 24 hours; this improvement persisted for 8 weeks in 58% of joints. A decrease in need for clotting factor was shown in this small group.

Noninflammatory Arthritis

Corticosteroid injection is used frequently in common non-inflammatory articular conditions such as osteoarthritis, internal derangements, and post-traumatic arthritis. Clinical studies that support efficacy are less convincing and suggest a less predictable and smaller degree of response in these conditions than is seen in inflammatory arthritis. Most studies of steroid injections in osteoarthritis have studied patients undergoing knee injections.²⁵ Early uncontrolled studies suggested improvement in approximately 60% to 80% of patients.⁶ In controlled studies, most benefit, compared with placebo, seems to last 1 to 6 weeks, with return to the same pain levels seen in placebo groups by around 12 weeks after injection.²⁶⁻²⁹

Factors associated with a better response to steroid injections have included less severe radiographic changes, the presence of effusion at the time of injection, and successful aspiration of fluid at the time of injection. The theoretic concern about the potential for negative effects of injected steroids on cartilage (discussed in the following section) is often cited as a reason to limit injections in osteoarthritis and other forms of noninflammatory arthritis. A more recent trial in 68 patients comparing corticosteroid injections every 3 months with saline injections showed no worsening of radiographic changes, however, after 2 years of repeated steroid injection, along with significant improvement in symptoms during the period of study.³⁰

Injections in patients with osteoarthritis of the hip are less likely to be helpful and are more technically difficult. Some relief can be obtained, however, in patients with less severe disease or in a rare patient with more severe involvement. A prospective, open study of intra-articular steroid in 45 patients with hip arthritis, 27 of whom had osteoarthritis, found a significant reduction in pain at 2 weeks and 12 weeks, although the effect was lost by 26 weeks.³¹ In a report of 510 patients treated with a single injection done under fluoroscopic guidance, pain relief that persisted

8 weeks was seen in 90% of patients with mild disease, 58% of patients with moderate disease, and 9% of patients with severe hip osteoarthritis; improved range of motion was shown in most of the patients responding.³² Controlled trials have shown that steroid injection provides modest benefit compared with placebo for 2 to 12 weeks, and the benefit was no longer apparent at 3 months.^{33,34} Steroid injection followed by non-weight bearing was not helpful in reducing the need for hip replacement in a retrospective study of patients with rapidly progressive osteoarthritis of the hip.³⁵ In patients with osteoarthritis of the thumb, local steroid injection may be helpful for 1 year in a few patients ($\approx 20\%$), but most patients are improved for 1 to 3 months at the most.³⁶

Injectable hyaluronic acid derivatives have been studied extensively and are frequently used for injection into osteoarthritic knees and occasionally in other joints. A series of one to five weekly injections has been shown to provide more pain relief than placebo in most studies. The degree and duration of improvement in these studies have varied, however, and the optimal role for hyaluronic acid injections in the management of arthritis has yet to be determined (see later discussion and Chapter 100).^{37,38}

Nonarticular Conditions

Patients with various forms of tendinitis, bursitis, myofascial pain, and nerve entrapment syndromes are frequently treated with local injections of corticosteroids.³⁹ In many of these conditions, uncontrolled clinical experience suggests a high response rate, and in many others, controlled trials show variable levels of benefit, often depending on whether short-term or long-term outcomes are considered. The injection of trigger points for pain relief has been used by many practitioners over the past several decades, but few controlled studies to support efficacy have been published.

Steroid injections are frequently used in the management of rotator cuff tendinitis, frozen shoulder, and other causes of shoulder pain. Most controlled studies have shown significant short-term improvement from steroid injection compared with placebo injection, usually lasting 4 to 6 months.⁴⁰ In most such trials, short-term treatment success of 75% to 80% is usually reported in steroid-treated groups compared with 40% to 50% in placebo groups. Most, but not all, controlled studies have shown that steroid injections are superior to physical therapy without injection, and that combining steroid injection with physical therapy has an additive benefit.⁴¹⁻⁴³ In a subset of patients with painful shoulder related to calcific tendinitis, local injection of ethylenediamine tetra-acetic acid (EDTA) may result in pain relief and radiographic resolution of calcification.⁴⁴ Local injections may also be useful for shoulder pain related to the acromioclavicular joint.

Lateral epicondylitis is also commonly treated by local injections.⁴⁰ Pain may worsen for 1 or 2 days after injection but usually improves after 4 to 5 days.⁴⁵ Longer controlled studies typically document improvement of 90% compared with 50% in placebo treatment in the first 1 or 2 months after injection, but outcomes at 6 to 12 months are usually not affected and one study has shown that recurrences of pain after 6 weeks were more common in patients who had steroid injections.^{46,47} Local injection of botulinum toxin

has been shown to be beneficial compared with placebo for epicondylitis in small trials.⁴⁸ In femoral trochanteric pain syndromes (i.e., bursitis), the response rate to locally injected steroids has been reported to be 60% to 100%, but no placebo-controlled studies have been done. A prospective study reported significant improvement after a single injection in 77% of patients at 1 week; this number decreased to 69% at 6 weeks and 61% at 26 weeks.⁴⁹ Patients receiving larger amounts of locally injected steroid (24 mg of betamethasone) were more likely to have sustained improvement. Around the knee, anecdotal and retrospective studies have shown that most patients with anserine bursitis respond to local steroid injection.

Local steroid injection may be a useful nonsurgical therapy for carpal tunnel syndrome. Most studies report 90% short-term relief of symptoms from a single injection; longer-term relief is 20% to 90%, and surgery is eventually required in about half of patients treated with injection. Controlled trials comparing local steroid injection with surgical decompression have shown variable results, suggesting that injection may provide better relief within the first 3 to 6 months, but more patients benefit from surgery when followed for 6 to 12 months.^{50,51} A good response to local injection is sometimes useful as a diagnostic test and is a predictor of good surgical response. As noted later, care should be taken to avoid injection into the body of the median nerve.⁵²

Most patients with de Quervain's tenosynovitis involving the tendons at the base of the thumb respond to local steroid injection. In three prospective studies, 60% to 76% of patients with this condition had their symptoms adequately controlled with a single injection, and another 10% to 33% required a second injection.^{53,54} About 30% had exacerbations an average of 1 year later, but overall, only 10% to 17% of patients were not controlled and required surgical release. Another small controlled study showed that injection was much better than splinting.⁵⁵ In patients with flexor tenosynovitis, steroids are effective in 88% compared with 36% of patients receiving saline injections, with improvement lasting for up to a year in most.⁵⁶ Similar success rates have been reported in prospective studies of patients with ganglion cysts.⁵⁷

In the ankle and foot area, injection therapy has been used to treat plantar fasciitis, tarsal tunnel syndrome, Achilles tendinopathy or bursitis, and interdigital neuroma (Morton's neuroma). Most of the data about efficacy for these conditions are anecdotal and uncontrolled. Generally, the response in tarsal tunnel syndrome is temporary, whereas the response in Morton's neuroma is more often prolonged. Reported response rates for plantar fasciitis vary, but one controlled trial showed a significant improvement at 1 month compared with placebo, whereas results were no different from placebo at 3 months.^{58,59} Studies of the efficacy of local corticosteroid injections for Achilles tendinopathy are inconclusive, and some have demonstrated an increased risk for Achilles tendon rupture.⁶⁰

Local injections for neck pain and low back pain have been used for many years, with anecdotal reports of improvement, but controlled or prospective studies have shown variable results, depending on patient selection and methodology. Few controlled studies have assessed local trigger point or other soft tissue injections in the paracervical or

paralumbal areas. Most studies of radiographically assisted facet joint injection of steroids in the lumbar or cervical areas show no difference compared with placebo, facet block, or local paraspinal injections.⁶¹⁻⁶³ Injections of the sacroiliac joint in patients with noninflammatory pain have shown a slight benefit from steroids compared with lidocaine alone.

PREPARATIONS

Corticosteroids

All hydroxycorticosteroid preparations are effective for intra-articular and periarticular injections (Table 54-3). The originally injected hydroxycortisone acetate is still available, widely used, and inexpensive. Triamcinolone hexacetonide is one of the least soluble agents with the presumed most prolonged effect. Not all preparations are equivalent in efficacy or duration of effect, but few studies have been done to compare the efficacy of the various preparations. More recent reports have shown that methylprednisolone is superior to triamcinolone acetonide, that triamcinolone hexacetonide has a more prolonged response compared with triamcinolone acetonide, and both of these are more effective than hydrocortisone.^{64,65} Most clinicians have become familiar with certain preparations and have continued to use these with efficacy for years. Some clinicians prefer to inject combinations of short-acting and long-acting preparations. Steroid preparations are often mixed with local anesthetics, particularly for injecting small joints, tendon sheaths, and periarticular structures. Mixing with a local anesthetic reduces the local discomfort of injection into a confined space and dilutes the concentration of the locally injected steroid and reduces the risk of soft tissue atrophy. Guidelines for the dosage of steroid injected into given joints are based roughly on the size of the joint

injected. Although no consensus exists regarding these amounts, most experts suggest injecting 1 mL of steroid preparation into large joints, with smaller amounts into smaller joints.

Other Injectable Products

Over the years, many other agents have been injected into joints including salicylates, phenylbutazone, gold, orgotein, progesterone, glycosaminoglycan polysulfate, and various antibiotics, but most have been abandoned because of lack of efficacy or local reactions. Various cytotoxic agents have been used sporadically or in small numbers of patients for intrasynovial tumors and refractory proliferative synovitis including nitrogen mustard, osmic acid, and methotrexate. Radioactive preparations (yttrium-90, colloidal ³²P chromic phosphate, dysprosium-165-ferric hydroxide, rhenium-186) have been used in both inflammatory and noninflammatory arthritis in occasional reports, but the evidence for efficacy and safety of these substances in patients with arthritis is limited.⁶⁶

Intra-articular hyaluronic acid preparations have been in use for many years in Europe and more recently in Canada and the United States. Several preparations of hyaluronic acid are approved for the treatment of osteoarthritis of the knee and seem to be superior to placebo injections in most, but not all, clinical trials, although no evidence for long-term efficacy or disease modification has been reported.^{37,38,67-69} These preparations are usually given weekly in a series of three to five injections, and more recent studies have used single injections or higher molecular weight preparations.⁷⁰ In direct comparisons with corticosteroids, hyaluronate is generally less effective in the first 4 weeks but more effective between 8 and 26 weeks after injections.⁷¹ Studies of hyaluronic acid preparations in osteoarthritic knees, hips, and shoulders have shown inconclusive or minimal levels of improvement.^{33,72} Hyaluronate injections may also be more effective than placebo in knees in rheumatoid arthritis and chronic painful rotator cuff disease, although these uses have not been as extensively studied.

Other injectable substances recently studied in small series for various conditions include botulinum toxin (for tennis elbow, painful shoulders, postoperative knee pain, and small joints in rheumatoid arthritis), EDTA for calcific tendinitis,⁷³ and collagenase for Dupuytren's contractures.⁷⁴ In addition, platelet-rich plasma has been used for soft tissue injuries (e.g., Achilles tendinopathy, tennis elbow) with variable results in controlled studies.⁷⁵

CONTRAINDICATIONS

There are few contraindications to diagnostic arthrocentesis (Table 54-4). Established infection such as cellulitis in periarticular structures is generally considered to be an absolute contraindication to inserting a needle into a joint. If inflammation in an underlying joint or bursa is thought to be the cause of the appearance of infection, however, aspiration of the joint or bursa should be attempted. Septicemia carries the theoretic risk of introducing blood-borne bacteria into a joint, but such complications are not well documented and joints suspected of being infected should be aspirated regardless of the presence of septicemia. Arthrocentesis

Table 54-3 Injectable Preparations for Intra-articular Injection

Corticosteroids	Prednisone Equivalent (mg/mL)
Betamethasone sodium phosphate (6 mg/mL)	50
Dexamethasone sodium (4 mg/mL)	40
Dexamethasone acetate (8 mg/mL)	80
Hydrocortisone acetate (24 mg/mL)	5
Methylprednisolone acetate (40 mg/mL)	50
Prednisolone terbutate (20 mg/mL)	20
Triamcinolone acetonide (40 mg/mL)	50
Triamcinolone hexacetonide (20 mg/mL)	25
Hyaluronic Acid (Indicated in Osteoarthritis of Knee)	
Hyaluronate Derivatives	
Euflexxa: inject 20 mg (2 mL) once weekly for 3 wk	
Hyalgan: inject 20 mg (2 mL) once weekly for 5 wk; some may benefit with a total of 3 injections	
Orthovisc: inject 30 mg (2 mL) once weekly for 3-4 wk	
Supartz: inject 25 mg (2.5 mL) once weekly for 5 wk	
Hylan Polymers	
Synvisc: inject 16 mg (2 mL) once weekly for 3 wk (total of 3 injections)	
Synvisc-One: inject 48 mg (6 mL) one time	

Table 54-4 Contraindications to Arthrocentesis and Joint Injection

Contraindication	Comment
Established infection in nearby structures (e.g., cellulitis, septic bursitis)	Sometimes gout mimics cellulitis, creating a confusing picture
Septicemia (theoretic risk of introducing organism into joint)	Need to tap suspected septic joints in septic patients
Disrupted skin barrier (e.g., psoriasis)	Do not tap through lesions
Bleeding disorder (not absolute, but use more care)	Risk of bleeding very low, even in patients taking warfarin
Septic joint	Steroid injection contraindicated
Prior lack of response	Relative contraindication
Difficult-to-access joint	Relative contraindication without imaging aid

through an area of irregular or disrupted skin, as seen in psoriasis, should be avoided because of the increased numbers of colonizing bacteria in these areas. Caution should be exercised in patients with bleeding disorders or patients taking anticoagulants, owing to the theoretic risk of inducing hemarthrosis. The risk of significant hemarthrosis after arthrocentesis is low, however, even in patients on regular warfarin therapy with international normalized ratios of 4.5.⁷⁶

COMPLICATIONS

Iatrogenic infection is the most serious, but least common, complication of arthrocentesis and joint injection (Table 54-5). In Hollander's large series,⁶ an incidence of infection of 0.005% was reported in a series of 400,000 injections. Gray and colleagues⁷⁷ reported an incidence of 0.001% several years later. An infection rate of 1:2000 to 1:10,000 (0.01% to 0.05%) has been noted in patients with rheumatoid arthritis, occurring exclusively in debilitated patients on immunosuppressive therapy.⁷⁸ A recent national database review in Iceland has estimated an infection rate of 0.037% from arthrocentesis.⁷⁹ Few other prospective or systematic studies of infection after arthrocentesis have been published, but most reported anecdotal experience has noted a similar low incidence of this serious complication.⁸⁰ An arthroscopic study showed that a small fragment of skin stained with a surgical marking pen could be identified within the joint space after most percutaneous insertions of a needle into the joint space, with identifications of bacterial nucleic acid by polymerase chain reaction in about one third of these.⁸¹ Considering the rarity of joint infection after arthrocentesis, these findings suggest that bacteria introduced at the time of arthrocentesis are either not viable or quickly cleared in almost all cases.

The most common complications of local steroid injections are related to local irritation of synovial and subcutaneous tissues and atrophy of soft tissues. Postinjection "flare" may develop in 1% to 6% of patients a few hours after injection and may last 48 hours, sometimes mimicking iatrogenic infection.^{6,8,82} These flares are reportedly more common with needle-shaped crystals and are believed to be similar

to the acute arthritis related to other crystals phagocytosed by leukocytes, but they may also be caused by preservatives in some steroid suspensions.

Weakening of tendons and tendon rupture have also been reported as a result of locally injected steroids,⁸³ emphasizing the importance of avoiding direct injection of steroids into the body of tendons. Most reports of tendon rupture have been anecdotal and described in patients involved in athletic activities or with rheumatoid arthritis. The risk of tendon rupture has not been adequately determined, but it seems to be quite low in the hands and wrists, where no ruptures were seen in a series of more than 200 injections⁸⁴ and only 2 were seen in another series of 956 injections.⁸ Areas believed to be at highest risk for rupture include the Achilles tendon, bicipital tendon, and plantar fascia, where the risk of rupture has been estimated to be 10%.⁸⁵

Systemic absorption occurs with locally injected depot corticosteroids. Since the earliest intra-articular injections of steroids, an anti-inflammatory effect has been shown not only in the injected joint but also in other joints in the same patient.⁴ Subsequent studies have documented decrease in plasma cortisol and suppression of the hypothalamic-pituitary axis lasting 2 to 7 days after a single injection. The degree and duration of adrenal suppression from a single intra-articular dose of depot steroid is less pronounced than that seen from an equal intramuscular dose.⁸⁶ In a study of

Table 54-5 Potential Complications of Arthrocentesis and Joint Injection

Complication	Comment
Iatrogenic infection	0.01%-0.05%; may be higher in RA patients
Postinjection "flare"	1%-6%; lasting 48 hr; may be related to preparation
Local soft tissue	May occur 1-6 mo later; pigment change
Local nerve damage	In structures near prominent nerves (e.g., carpal tunnel syndrome)
Tendon rupture or weakening	Case reports; animal studies show highest risk in Achilles tendon and plantar fascia
Systemic steroid absorption	Inevitable; usually subclinical Hypothalamic-pituitary suppression 2-7 days; changes in bone formation 14 days Flushing; facial warmth; diaphoresis Transient elevation of blood glucose; lymphopenia; eosinopenia
Avascular necrosis of bone	Controversial; reported but usually explained by underlying disease or systemic steroids in same patient (ischemic necrosis)
Negative effects on cartilage	Controversial Found in animal models of normal cartilage but not in primates Case reports in humans receiving multiple injections Some animal models of arthritis are better with steroid injections Large human observational studies have not documented more problems than expected (osteoarthritis, RA, juvenile RA)

RA, rheumatoid arthritis.

markers of bone turnover, a single injection of triamcinolone in knees of rheumatoid arthritis patients resulted in no change in bone resorption markers but yielded a drastic reduction in markers of bone formation within 1 day, which returned to normal levels in 14 days.⁸⁷ A transient and variable effect on blood glucose levels after local steroid injection has also been observed in small studies, and unsurprisingly, this appears to be more pronounced in patients with diabetes.⁸⁸

Some patients experience prominent erythema, warmth, and diaphoresis of the face and torso within minutes to hours after steroid injections.⁸³ This reaction is most likely related to systemic absorption, but idiosyncratic reaction to preservatives in steroid preparations has also been implicated. Similarly, some patients may experience other typical metabolic effects of systemic steroids such as transient increases in blood glucose or decreases in peripheral blood eosinophil or lymphocyte counts.

Avascular necrosis of bone (ischemic necrosis) has long been considered a potential complication of intra-articular steroids, with a reported prevalence of this complication in injected joints ranging from less than 0.1% to 3%.^{6,18,23} Most studies have suggested, however, that the occurrence of this complication is related more to the severity of the associated disease or systemic steroid therapy and is unrelated to local injections.

The potential for negative effects of locally injected corticosteroids on cartilage metabolism has been a controversial area of study for several decades. Anecdotal reports of Charcot-like arthropathy attributed to intra-articular steroids first appeared in the late 1950s and 1960s, often occurring in patients having more than 10 (and sometimes hundreds) joint injections over many months or years. Several studies in the 1960s and 1970s showed that locally injected steroids caused destructive changes, catabolic effects, or both in normal animal cartilage.^{89,90} These included findings of decreased protein and matrix synthesis with degenerative cellular changes in chondrocytes, as well as fissures and decreased proteoglycan content in cartilage matrix. Similar studies done in primate joints failed to show any negative effects from intra-articular corticosteroids, however.⁹¹

Studies done in subsequent years have shown protective effects on cartilage lesions and reduction in osteophyte development in animal models of experimentally induced osteoarthritis, as well as associated reduction in metalloproteinase levels in cartilage and an increase in lubricating synovial surfactant.^{92,93} In humans with osteoarthritis, intra-articular steroids have been shown to decrease macrophage infiltration of the synovial lining, but no change was noted in metalloproteinase levels.⁹⁴ Observations in humans treated with frequent corticosteroid injections have yielded conflicting information regarding changes in articular cartilage. More recent observations in patients with oligoarticular juvenile rheumatoid arthritis, mentioned previously, suggest that frequent steroid injections have the potential to help protect cartilage from the destructive process of the underlying disease process and are not associated with negative effects on articular cartilage.^{19,21,23} In addition, a study of patients with rheumatoid arthritis has shown no increase in the need for subsequent joint replacement surgery in the joints receiving four or more injections in a 1-year period.⁹⁵

GENERAL ARTHROCENTESIS TECHNIQUES

Materials

Most practitioners find that an arthrocentesis tray containing needed items allows more flexibility in preparing for aspirating or injecting joints or other articular structures. Syringes greater than 20 mL are not necessary for most procedures, but a swollen knee may occasionally contain 60 mL or more of fluid and it is reasonable to have at least one syringe of this size in a tray, with others available for rare patients with effusions greater than 100 to 200 mL in volume. Heparinized or citrated tubes to prevent coagulation of inflammatory fluids for accurate cell counts and crystal analysis, plain tubes for chemistry evaluations, and sterile tubes for transporting fluid to a microbiology laboratory for culture should be included. In joints being aspirated for the presence of bacteria and crystals, small amounts of fluid or debris may be present in the bore of the needle, even when no obvious fluid is obtained. In such situations, it is best to have clean microscope slides and coverslips available at the bedside for microscopic examination for cellularity, Gram stain, and crystals.

A hemostat is helpful for changing syringes after aspiration to inject corticosteroid. The size and length of needles used depend on the anticipated amount of fluid to be obtained from a joint and the size of the involved joint. A 20- to 22-gauge needle is usually sufficient to aspirate most detectable effusions, but large effusions with large amounts of debris, as seen in septic joints, may require larger-bore needles. In small joints, a 23- to 27-gauge needle may be used, particularly when no fluid appears to be present, and only therapeutic injection is being considered. A needle 1½ inches in length is adequate for almost all procedures, but a 3-inch spinal needle may occasionally be necessary for a large knee or hip.

Site Preparation and Technique

Sterile technique designed to avoid the introduction of skin bacteria into the joint should be observed in all procedures, although precautions taken to avoid infection in clinical practice vary widely.⁸⁰ After careful examination and identification of the specific point of aspiration, this point may be marked by the end of a ballpoint pen with the writing point retracted. The area should be carefully cleaned with one or two layers of iodine followed by alcohol. These precautions are sufficient to minimize the risk of infection, although a single “swipe” of isopropyl alcohol has been shown to provide a similar level of protection.⁹⁶

A physician experienced in arthrocentesis may elect to not use topical anesthesia in many patients because the amount of pain is often no more than that experienced from phlebotomy. In an anxious patient or when small joints or joints with minimal fluid are being aspirated, topical anesthesia may be attained by the use of spray coolant (ethyl chloride) or an intradermal wheal and subcutaneous infiltration of lidocaine. Spray coolant may be applied after sterile preparation and has been shown to not contaminate the field.⁹⁷ In pediatric patients, particularly when multiple joints are injected, sedation or general anesthesia may be required for safe and accurate injections.⁹⁸ Nonsterile gloves

should be worn by the operator to avoid contamination with the patient's synovial fluid or blood. Drapes and sterile gloves are unnecessary, but the gloved hand should not touch the prepared site. A joint is usually entered at a 90-degree angle to the skin, slowly and evenly, and negative pressure should be applied to the syringe when the needle has been advanced $\frac{1}{2}$ to 1 inch (in a large joint). If the needle's course is obstructed by bone, the needle should be withdrawn slightly and redirected at a slightly different angle. If no fluid is obtained, the needle should be slowly advanced and negative pressure continued. If fluid flows initially and then stops, the needle may be advanced or retracted slightly or rotated in case it is blocked by an intra-articular structure or synovial tissue. After an adequate amount of fluid is obtained, a hemostat may be used to secure the needle, the syringe may be removed, and a new syringe with injectable steroid may be attached if injection is indicated. Overall accuracy of arthrocentesis has been estimated to be between 80% and 100% using anatomic landmarks in most joints.⁹⁹ In "dry joints" a "backflow technique," in which saline is injected and then aspirated back, may be used to help confirm correct needle positioning.¹⁰⁰ A three-way stopcock is preferred by some practitioners when aspiration and injection are performed in the same setting.¹⁰¹

After injection, the needle and syringe should be removed and pressure applied over the site until a bandage is applied. When synovial fluid is to be examined for crystals, care should be taken to not replace the needle used for steroid injection on the syringe with synovial fluid because the contamination of fluid with steroid crystals would make accurate identification of urate and calcium pyrophosphate crystals more difficult. In some situations, positioning the barrel of the syringe and simultaneous aspiration may result in difficulty controlling needle position, and a newly available one-handed reciprocating syringe may allow for better operator control of the syringe in more difficult aspirations.^{102,103}

Postprocedure Instructions and Care

After the procedure, patients should be reminded about the risk for postinjection "flare" within 24 to 48 hours after local steroid injection. If pain, redness, or swelling progress afterward, are particularly severe, or are accompanied by fever, the patient should be instructed to call and be re-evaluated for the remote possibility of iatrogenic infection. Patients should also be reminded about the soft tissue atrophy and hypopigmentation that may occur weeks to months after the procedure, particularly when structures close to the skin are injected. For patients in whom tendon sheaths are injected, heavy activities using the involved tendons should be avoided for several days.

After injection of joints, particularly weight-bearing joints, activities should be limited owing to evidence that activity restriction prolongs the effect of the injected steroid. In a large series reported in 1995, McCarty and colleagues⁸ used a regimen that emphasized 3 weeks of splinting for upper extremity joints and 6 weeks of crutch walking for lower extremity joints, suggesting that rest after the injection was important in prolonging the effect of injections. Several other retrospective studies and anecdotal

observations have suggested a role for strict rest or non-weight bearing after injection to improve duration of efficacy.¹⁰⁴ One small controlled study showed that rest provided no advantage over regular activities in regard to short-term or long-term outcomes.¹⁰⁵ In a larger prospective controlled trial of knees in patients with rheumatoid arthritis, a 24-hour period of strict bed rest after injection resulted in a more prolonged improvement, however, compared with patients who were not restricted.¹⁰⁶ A similar study of elbow injections showed no benefit from sling immobilization.¹⁰⁷ Most practitioners advise restricted activities after steroid injections, particularly in weight-bearing joints, but opinions on the relative importance of rest after injections still vary and no specific regimen of rest would be considered standard practice among physicians.

SPECIFIC REGIONAL ARTHROCENTESIS TECHNIQUES

Cervical Spine Area

Most injections in the region of the cervical spine, trapezius, and scapular areas are best considered to be myofascial or trigger point injections. The point of injection is usually determined by palpating for the areas of most tenderness, and few reliable landmarks are available for localization of anatomic structures. Using a 22- to 25-gauge needle, a combination of 0.5 mL of steroid and 0.5 to 2 mL of lidocaine can be injected into areas in the paracervical muscles or other areas where tenderness can be elicited. Some of the injections done in these areas are likely to be close enough to the posterior cervical facet joints to reduce inflammation in the joints themselves, whereas others probably reduce inflammation in ligaments, tendons, or bursal structures. More precise injection of posterior cervical facet joints may be accomplished under fluoroscopic visualization.⁶³

Anterior Chest Wall

The anterior chest area occasionally may be the site of inflammatory disease of the sternoclavicular joints. It is usually difficult to obtain much fluid for diagnostic purposes from this joint, but a few drops for microscopic analysis and culture may be available in some patients. The point of aspiration should be dictated by the point of maximal swelling near the surface. Aspiration should be attempted with caution, using as short and small a needle as possible to avoid damage to nearby vascular structures, lung, or airway. A small amount of steroid (0.1 to 0.5 mL) may be injected in this joint, as long as the suspicion of infection is low. In Tietze's syndrome, one or more of the anterior costochondral junctions may be swollen, but such areas do not contain fluid for analysis and should be approached with caution for injection of small amounts of steroid and lidocaine. Inflammation of the manubriosternal joint in patients with spondyloarthropathy may be improved by fluoroscopically guided injection.¹⁰⁸

Temporomandibular Joint

The temporomandibular joint may be involved in patients with rheumatoid arthritis, spondyloarthropathies, or

osteoarthritis, and internal derangement of this joint may be a source of discomfort usually treated by oral surgeons.¹⁰⁹ This joint is palpated as a depression just below the zygomatic arch about 1 to 2 cm anterior to the tragus. The depression is usually more easily palpated by having the patient open and close the mouth. After a mark is made over the area, a 22- to 25-gauge needle is inserted perpendicular to the skin and directed slightly posteriorly and superiorly; 0.1 to 0.25 mg of steroid preparation can be injected. This joint seldom has enough fluid for diagnostic aspiration.

Shoulder

Numerous structures in and around the shoulder may be involved in systemic processes, injury, or overuse syndromes, and each has the potential to benefit from local steroid injection. Ideally, injections should be directed toward specific anatomic sites on the basis of clinical findings. For practical purposes, injections into the glenohumeral joint or subacromial bursal space are often beneficial for pain related to other nearby structures such as the rotator cuff tendons or bicipital tendon.

Glenohumeral Joint

The glenohumeral joint may be entered from an anterior or posterior approach. For an anterior approach, the patient should be in a sitting position with the shoulder externally rotated (Figure 54-1). A mark is made just medial to the head of the humerus and slightly inferiorly and laterally to the coracoid process. A 20- to 22-gauge, 1½-inch needle is directed posteriorly and slightly upward and laterally. For a posterior approach, the upper arm should be against the lateral chest and forearm across the chest. A mark should be made about 2 inches inferior to the acromion. One should be able to feel the needle enter the joint space, but if bone is hit, the needle should be pulled back and redirected at a slightly different angle. When the joint is

Figure 54-1 Shoulder (glenohumeral) joint arthrocentesis: anterior approach. With the shoulder externally rotated, the needle is inserted at a point just medial to the head of the humerus, slightly inferior and lateral to the coracoid process (marked in black), which is just inferior to the lateral aspect of the clavicle (marked in black above).

Figure 54-2 Rotator cuff tendon/subacromial bursa injection: lateral approach. Over the lateral aspect of the shoulder, the groove between the acromion (marked in black) and humerus is palpated and marked (spot). The needle is inserted at this point and advanced in a horizontal plane medially.

entered, fluid should be aspirated, if present, and the joint should be injected with 1 mL of steroid preparation, with or without 1 to 3 mL of lidocaine.

Acromioclavicular Joint

The acromioclavicular joint, similar to the sternoclavicular joint, is composed of fibrocartilage and rarely contains fluid. The joint is palpated as a groove at the lateral end of the clavicle, just medial to the tip of the acromion, and may display some degree of soft tissue swelling or bony prominence, depending on the underlying disease process. To enter the joint with a needle, a mark should be made over the groove, and a 22- to 25-gauge needle should be introduced 1 inch or less. After an attempt to obtain fluid, 0.25 to 0.5 mL of steroid preparation may be injected.

Rotator Cuff Tendon and Subacromial Bursa

The rotator cuff tendon and subacromial bursa area may be entered using a 22- to 25-gauge needle, usually 1½ inches in length (Figure 54-2). Over the lateral or posterolateral aspect of the shoulder, the groove between the acromion and humerus should be palpated and marked. The needle is inserted at this point and advanced in a horizontal plane medially, usually 1 to 1½ inches. It is unusual to obtain fluid from this space. In most cases, the area is injected without aspiration; usually 1 mL of steroid preparation with 1 to 3 mL of lidocaine are injected to allow wider distribution of medication in this area.

Bicipital Tendon

Bicipital tendinitis may be treated by injecting the shoulder joint or the tendon sheath itself. If the tendon is to be injected, it can be palpated over the anterior aspect of the shoulder in the bicipital groove of the shoulder; it is usually tender and can be rolled under the examiner's finger. A 22-gauge, 1½-inch needle should be inserted in the sheath, and portions of the steroid and lidocaine

Figure 54-3 Elbow arthrocentesis. With the elbow flexed 90 degrees, the needle is inserted into the recess just below the lateral epicondyle (black circle) and radial head (black line) and is directed parallel to the shaft of the radius.

preparation should be injected directly, and then superiorly and inferiorly, along the course of the tendon after redirecting the needle in each direction. Discretion is advised, however, when considering injection of this tendon sheath because there may be increased risk of tendon rupture in this area.

Elbow

Elbow Joint

The elbow is best entered by insertion of the needle into the area over the lateral elbow where a bulge can be palpated if fluid is present within the joint (Figure 54-3); this is best determined with the elbow flexed at 90 degrees. A mark should be made just below the lateral epicondyle in the groove just proximal to the head of the radius and above the olecranon process of the ulna. After preparation, a 20- to 22-gauge needle held perpendicular to the skin is inserted approximately 1 inch, and the joint is aspirated, followed by injection if indicated.

Medial and Lateral Epicondyle

The areas of the medial and lateral epicondyle are commonly affected by overuse syndromes involving the origins of muscle groups of the forearm, particularly the lateral epicondyle, which is the area of inflammation in tennis elbow (Figure 54-4). With the elbow flexed, the area of tenderness over the anterolateral surface of the external condyle of the humerus should be marked. After preparation, a 22- to 25-gauge needle 1 to 1½ inches long should be inserted about 1 to 2 cm distal to the mark; 0.5 mL of steroid preparation mixed with 1 to 3 mL of lidocaine is administered in several small doses after partially withdrawing and redirecting the needle and reinjecting in two to three passes of the needle in the area. Injections in this area often deliver steroids to subcutaneous tissues close to the skin, and patients should be advised about the likelihood of subcutaneous atrophy and pigment changes that may occur

weeks or months after the injection. The medial epicondyle is injected in a similar fashion, with more care required to avoid inadvertent injection of steroids into the area of the ulnar groove just behind the bony prominence of the epicondyle.

Olecranon Bursa and Nodules

The area of the olecranon bursa and nodules is located just under the skin over the tip of the olecranon process at the posterior aspect of the elbow. Swelling in this area is detected easily as a localized collection of fluid and can be easily aspirated and injected if fluid is present. A smaller-gauge needle (22 to 23 gauge) may be used for noninflammatory processes, but a larger gauge (20-gauge) is often necessary for bursal effusions related to rheumatoid arthritis or gout. After preparation, the needle should be inserted under the skin into the easily palpable area of fluid, and as much fluid as possible should be aspirated. For noninfectious processes, 0.5 to 1 mL of steroid can be injected into the space. Subcutaneous nodules in this area, or at other locations around the body, may be aspirated for diagnostic purposes, usually to differentiate rheumatoid nodules from tophi. For this type of aspiration, an 18- to 20-gauge needle is inserted into the nodule and rotated, retracted to near the surface, and then reinserted and rotated, with negative pressure applied on the syringe. After removal, the contents of the syringe should be expelled onto a microscope slide and may be examined for cellular content and crystals.

Wrist and Hand

Radiocarpal Joint

The wrist joint is complex, but most of the intercarpal spaces communicate with the radiocarpal joint, which may be entered from a dorsal approach. A mark should be made just distal to the radius and just ulnar to the “anatomic snuffbox” (Figure 54-5). A 22- to 25-gauge needle, ½ to 1

Figure 54-4 Lateral epicondyle (tennis elbow) injection. With the elbow flexed and pronated, the needle is inserted at the most tender area over the bony prominence on the anterolateral aspect of the lateral humerus, which is proximal to radial head (black line). A combination of steroid and local anesthetic is injected into the subcutaneous tissues at the attachment of the extensor muscles to the epicondyle.

Figure 54-5 Wrist (radiocarpal) arthrocentesis. The needle is inserted just distal to the radius (marked in black) at a point just ulnar to the anatomic snuffbox. It is directed perpendicular to the skin and advanced until fluid is obtained or the needle is advanced 1 to 1.5 inches.

inch long, is usually adequate. Occasionally, 3 to 5 mL of fluid may be obtained from the wrist by aspiration, and, if indicated, 0.5 mL of steroid may be injected into the space.

Dorsal Wrist Tendons

The extensor tendon sheaths over the dorsal wrist may become inflamed and swollen secondary to numerous inflammatory processes, most commonly rheumatoid arthritis, but occasionally crystal-induced arthritis or infectious processes. The areas of swelling are well defined and close to the surface, and they are entered easily with a direct aspiration, usually at a 30- to 45-degree angle, with the needle directed along the course of the swollen tendon. Fluid is often easily obtained, but in some patients, in particular, patients with rheumatoid arthritis, proliferative synovial tissue limits the amount of fluid that can be aspirated. After aspiration, the area can be injected with 0.5 mL of corticosteroid mixed with 0.5 to 1 mL of lidocaine, if indicated.

de Quervain's Tenosynovitis

de Quervain's tenosynovitis, a common overuse syndrome involving the tendons at the radial aspect of the anatomic snuffbox, is often helped by local injection of the tendon sheath. After examination, the area of greatest tenderness along the course of the tendon should be marked, and the needle should be inserted almost parallel to the skin, either proximally or distally (Figure 54-6). As the needle is advanced, 0.5 mL of steroid with 0.5 to 2 mL of lidocaine can be injected along the sheath of the tendon, and a palpable bulge is usually felt along the tendon. Care should be taken to avoid injection of steroid into the body of the tendon by moving the needle slightly if resistance to injection is noted.

Carpal Tunnel Syndrome

Inflammation with swelling in the many flexor tendons in the carpal tunnel area may result in median nerve

Figure 54-6 Injection for de Quervain's tenosynovitis. The needle is inserted along the course of the tendons (black line), proximal to the thumb carpometacarpal joint (spot), at the radial aspect of the anatomic snuffbox. The needle is directed almost parallel to the skin either proximally or distally. As the needle is advanced, a mixture of steroid and anesthetic is injected along the sheath of the tendon and a palpable bulge is usually felt along the tendon. Care should be taken to avoid injection of steroid into the body of the tendon.

compression, and injection in this area has the potential to relieve symptoms by reducing this inflammation (Figure 54-7). This area should be injected by making a mark on the volar aspect of the wrist along the flexor carpi radialis tendon (on the radial side of the long palmar tendon), approximately 1 to 2 cm proximal to the distal wrist crease.¹¹⁰ A 22- to 26-gauge needle may be introduced perpendicular to the skin or, alternatively, at a 30- to 45-degree angle, directing the needle proximally or distally along the course of the tendon. The needle should be introduced about $\frac{1}{2}$ to 1 inch, and the area is injected with 0.5 mL of

Figure 54-7 Injection for carpal tunnel syndrome. To begin an injection in this area, the clinician should make a mark on the volar aspect of the wrist along the flexor tendons, on the radial side of the long palmar tendon, and approximately 1 inch proximal to the distal volar skin crease at the wrist (black marking). A 22- to 26-gauge needle is introduced at a 30- to 45-degree angle and is directed proximally or distally along the course of the tendon. The needle should be introduced about $\frac{1}{2}$ to 1 inch. If the needle meets obstruction or if the patient experiences paresthesias, the needle should be withdrawn and redirected slightly to avoid injecting into the body of a tendon or into the median nerve itself.

steroid with 0.5 to 1 mL of lidocaine. If the needle meets obstruction or if the patient experiences paresthesias, the needle should be withdrawn and redirected slightly to avoid injecting into the body of a tendon or into the median nerve itself.

Ganglia

Small, often hard, nodular structures known as ganglia are frequently present around the hands and wrists, and they may occur in many other areas near joints or tendons. These structures usually contain a thick, gelatinous substance that is difficult to aspirate. In cases in which pain, tendon dysfunction, or nerve entrapment symptoms are bothersome to the patient, aspiration may be attempted, usually with an 18- to 20-gauge needle. Even if no fluid is obtained, the process of puncture occasionally causes the structure to dissipate its contents and symptoms are relieved. A small amount (0.2 to 0.5 mL) of steroid with lidocaine may be injected in an attempt to prevent reaccumulation of fluid.

Thumb Carpometacarpal Joint

Aspiration of fluid from this joint is seldom possible and rarely indicated. This joint is commonly involved in osteoarthritis, however, and may be a source of localized pain amenable to local injection (Figure 54-8). The joint space is narrowed and often surrounded by osteophytes, but it may be entered accurately by flexing the thumb across the palm and making a mark at the base of the thumb metacarpal away from the border of the snuffbox.¹¹¹ A 22- to 25-gauge needle should be inserted $\frac{1}{2}$ to 1 inch at this mark and directed away from the radial artery; 0.2 to 0.5 mL of steroid may be injected.

Metacarpophalangeal and Interphalangeal Joints

Inflammation in the small joints of the hands usually causes the synovium to bulge dorsally. Occasionally, these small

Figure 54-8 Injection of the thumb carpometacarpal joint. The procedure begins by flexing the thumb across the palm and making a mark at the base of the thumb metacarpal distal to the radial tendons of the snuffbox (black). A 22- to 25-gauge needle is inserted $\frac{1}{2}$ to 1 inch at this mark and directed away from the radial artery; 0.2 to 0.5 mL of steroid may then be injected.

joints may have enough swelling for a drop or two of fluid to be obtained for crystal analysis, culture, or both. In most cases, arthrocentesis is performed for symptom relief; 0.1 to 0.2 mL of corticosteroid is injected, with or without local anesthetic. A 24- to 27-gauge, $\frac{1}{2}$ - to 1-inch needle can be inserted on either side of the joint at a mark made at the joint line, just under the extensor tendon mechanism. Some physicians prefer to have the joint slightly flexed to improve the chances for entry into the joint space itself.

Flexor Tenosynovitis (Trigger Fingers)

The pathologic process in this condition usually involves the tendon at the level of the metacarpophalangeal joint in the palm. Usually, a localized swelling that moves with the tendon sheath may be palpated in this area. After a mark has been made at this area, a 22- to 27-gauge needle may be introduced at a 30- to 45-degree angle, directing the needle proximally or distally along the course of the tendon. The needle should be introduced about $\frac{1}{2}$ inch, and the area may be injected with 0.5 mL of steroid with 0.5 mL of lidocaine. Lack of resistance during injection indicates proper needle placement, as is the case with other tendon sheath injections.

Lumbosacral Spine Area

Back pain is difficult to explain anatomically in most patients, but many patients with back pain have areas tender to deep palpation, particularly in the presacral area and paraspinal muscles. As is the case in the cervical spine area, most injections in this region are best considered to be myofascial or trigger point injections. The point of injection is usually determined by palpating for the areas of most tenderness, with few reliable landmarks available for localization of anatomic structures. Using a 22- to 25-gauge needle, a combination of 0.5 to 1 mL of steroid and 0.5 to 2 mL of lidocaine can be injected into areas of the paraspinal muscles or other tender areas. Some of the injections performed in these areas are likely to be close enough to the posterior lumbar facet or upper sacroiliac joints to reduce inflammation in the joints themselves, whereas others probably reduce inflammation in ligaments, tendons, or bursal structures. More precise injection of posterior lumbar facet or sacroiliac joints requires radiographic guidance, with fluoroscopy, CT, or MRI.⁶¹

Pelvic Girdle

Ischiogluteal Bursitis

The bursa over the ischial tuberosity is located by direct palpation in the buttock while the patient lies on the opposite side with knees fully flexed. The prominence is more easily palpated as the gluteus muscles are displaced from the area. After marking the area of tenderness over the prominence, a 3-inch needle should be inserted horizontally until bone is hit and 1 mL of steroid with 1 to 2 mL of lidocaine is instilled. Care should be taken to avoid the sciatic notch medially.

Trochanteric Pain Syndrome (Bursitis)

Trochanteric pain syndrome is diagnosed by physical findings of normal hip joint motion and a reproducible tender area in the region of the greater trochanter where the gluteal muscles insert (Figure 54-9). This area can be injected easily after marking the area of tenderness with the patient lying on the opposite side. A 1- to 3-inch needle should be inserted perpendicular to the skin of the bony prominence, and 1 mL of steroid with 2 to 4 mL of local anesthetic are injected into the area.

Hip (Acetabular) Joint

The hip is a difficult joint to aspirate and inject, and synovial fluid is seldom obtained from the hip in clinical practice. Two approaches can be attempted—either an anterior or a lateral approach—but accuracy of each varies. A cadaver study found the rate of correct needle placement was only 60% with the anterior approach and 80% with the lateral approach, and the anterior approach frequently resulted in needle placement in the vicinity of the femoral nerve.¹¹² Accuracy using a lateral approach may improve with experience.¹¹³ In situations where synovial fluid analysis is essential to patient management, particularly when infection is suspected, fluoroscopic guidance is necessary to obtain fluid for culture and other studies.

If aspiration without fluoroscopic guidance is attempted, a 20-gauge, 3-inch needle should be used. For the anterior approach, the patient should be supine with the hip fully extended and externally rotated. A mark should be made 2 to 3 cm below the anterior superior iliac spine and 2 to 3 cm lateral to the femoral pulse. The needle is inserted at a 60-degree angle and directed posteriorly and medially until bone is hit. The needle is withdrawn slightly, and an attempt should be made to aspirate fluid. Injection of 1 mL of steroid with lidocaine may follow if indicated. For a lateral approach (Figure 54-10), the patient should be supine and the hips

Figure 54-9 Injection for trochanteric pain syndrome. This area is easily injected after marking the area of tenderness over the bony prominence of the lateral hip with the patient lying on the opposite side. A 1- to 3-inch needle is inserted perpendicular to the skin over the bony prominence, and 1 mL of steroid with 2 to 4 mL of local anesthetic is injected into the area. (Anterior superior iliac spine is marked in black for reference.)

Figure 54-10 Hip arthrocentesis: lateral approach. With the hip internally rotated, the needle is inserted just anterior to the greater trochanter (black) and directed toward a point slightly below the inguinal ligament (anterior superior iliac spine is for reference). As noted in the text, accuracy of any approach to the hip joint is limited and radiographic guidance should be considered unless synovial fluid is easily obtained using this approach.

rotated internally with knees apart and toes touching. A mark should be made just anterior to the greater trochanter, and the needle should be inserted and directed medially and slightly cephalad toward a point slightly below the middle of the inguinal ligament. Often, the clinician can feel the tip of the needle slide into the joint, and aspiration can be attempted.

Knee

Knee Joint

The knee is the easiest joint to enter with certainty by arthrocentesis and is the joint most frequently aspirated for synovial fluid analysis in clinical practice. The knee may be aspirated with the patient in the supine or sitting position and from medial, lateral, or anterior aspects. Aspiration is usually considered to be easiest with the patient in the supine position with the knee almost fully extended. A mark should be made just posterior to the medial or lateral aspect of the patella in the recess behind the patella, where a bulge or “fluid wave” can be detected on physical examination if fluid is present (Figures 54-11 and 54-12). An 18- to 22-gauge needle should be directed posteriorly and slightly inferiorly, and fluid can be aspirated after advancing the needle $\frac{1}{2}$ to $1\frac{1}{2}$ inches into the joint space.

A lateral approach is preferred by some clinicians because more fluid can be removed from this side in many patients.¹¹⁴ In patients with rheumatoid arthritis or septic arthritis, synovial debris or proliferative synovial tissue may occlude the needle and it may be necessary to rotate the needle to facilitate aspiration. In some patients, the knee can be aspirated and injected with the patient in a sitting position with the knee flexed. A mark can be made just below the distal border of the patella in the recess on either side of the infrapatellar tendon. One more recent study showed that a lateral midpatellar approach had a higher accuracy rate than the anteromedial or anterolateral approaches done in a

Figure 54-11 Knee arthrocentesis: medial approach. With the patient supine, a mark is made in the recess (or where there is a fluid bulge) behind the medial portion of the patella (*black*), approximately at the midline. The needle should be advanced 1.5 inches or more until fluid is obtained (patellar tendon is for reference).

sitting position.¹¹⁵ Another recent study reported increased accuracy in more severely narrowed osteoarthritic knees using a modified Waddell approach (an anteromedial approach with manipulative ankle traction at 30 degrees of knee flexion).¹¹⁶

In some patients, the suprapatellar bursa may become distended with fluid. Because this space is an extension of the knee joint, either the knee joint or the suprapatellar bursa may be aspirated directly to remove fluid from this area. In some patients with large effusions, compression of the suprapatellar area allows more fluid to be obtained by arthrocentesis from the knee joint itself. In other patients, a popliteal cyst may form in the area behind the knee joint and there may often be a ball-valve leakage of fluid from the knee joint. The cyst may be difficult to aspirate sometimes because of its location or lack of distinct borders.

Figure 54-12 Knee arthrocentesis: lateral approach. With the patient supine, a mark is made in the recess (or where there is a fluid bulge) behind the lateral portion of the patella (*black*), approximately at the midline. The needle should be advanced 1.5 inches or more until fluid is obtained (patellar tendon is for reference).

Injection of corticosteroid into the knee joint usually results in the passage of medication into the cyst with a therapeutic effect.

Periarticular Knee Pain Syndromes

Pain related to the anserine bursa, located over the medial aspect of the tibia just below the joint line, can be treated with a local injection into this area. In addition, some patients may have an area of localized soft tissue tenderness above the joint line over the medial and lateral condyles, often believed to be related to an irritated iliotibial band (lateral) or infrapatellar plica (medial). In each of these conditions, the area of tenderness should be marked and a 22-gauge needle should be introduced to the bone and withdrawn slightly. The area should be injected with 0.5 mL of steroid with 1 to 3 mL of local anesthetic. Prepatellar bursitis may result in swelling in the soft tissues anterior to the patella and should be distinguishable from a knee effusion. Similar to olecranon bursitis at the elbow, this area may be aspirated directly at the point of maximal swelling. The area may be injected with 0.5 mL of corticosteroid preparation if indicated.

Ankle and Foot

Tibiotalar Joint

The tibiotalar joint is best aspirated with the patient in a supine position with the leg-foot angle at 90 degrees (*Figure 54-13*). A mark is made just medial to the tibialis anterior tendon and lateral to the medial malleolus. A 20- to 22-gauge, 1½-inch needle is directed posteriorly and should enter the joint space without striking bone. If resistance is felt and no fluid is obtained, the needle should be withdrawn to close to the surface and redirected slightly while aspirating for fluid. After aspiration, the area may be injected with 0.5 mL of corticosteroid, with or without lidocaine.

Figure 54-13 Ankle arthrocentesis: anterior approach (tibiotalar joint). With the ankle at a 90-degree angle to the lower leg, the needle is inserted at a point just lateral to the medial malleolus (*black marking*) and just medial to the tibialis anterior tendon. The needle is directed posteriorly, perpendicular to the shaft of the tibia.

Figure 54-14 Subtalar (lateral) ankle arthrocentesis. The needle is inserted into the recess just inferior to the tip of the lateral malleolus (black marking) and directed perpendicularly. A bulge is often easily palpated here if fluid is present in this joint.

Subtalar Joint

Swelling from the subtalar joint is usually detected by swelling beneath the lateral malleolus. A mark is made just inferior to the tip of the lateral malleolus, usually over the area of swelling. A 20- to 22-gauge needle should be directed perpendicular to the skin, and the area should be aspirated as the needle is advanced (Figure 54-14). The needle may be withdrawn partially and advanced again if no fluid is obtained with the first pass, and 0.5 mL of corticosteroid may be injected after fluid is aspirated, if indicated.

Achilles Tendon Area

Generally, the area around the insertion of the Achilles tendon on the calcaneus should not be approached with a needle. In some patients, an area of swelling may be detected, however, in the subcutaneous Achilles bursa between the skin and tendon or in the retrocalcaneal bursa between the tendon and calcaneus. In either case, the area may be aspirated for fluid analysis, using a lateral or medial approach for the deeper area, to avoid inserting the needle through the Achilles tendon. In rare patients, these areas or the sheath of the Achilles tendon itself may be injected with 0.25 to 0.5 mL of steroid preparation with lidocaine. As noted previously, any injection in this area should be undertaken with extreme care to avoid injection within the body of the Achilles tendon, owing to the risk and potential consequences of rupture.

Tarsal Tunnel Syndrome

Tarsal tunnel syndrome, an uncommon condition, is sometimes amenable to local steroid injection, although the optimal approach to therapy in this condition is uncertain. The skin should be marked just inferior and posterior to the medial malleolus. The tendon sheaths in this area may be injected with a 22- to 25-gauge needle with 0.5 mL of steroid and 0.5 to 1 mL of lidocaine. Care should be taken to not inject the nerve.

Plantar Fascia

Tenderness is usually elicited along the course of the plantar fascia and at its insertion at the calcaneus. This area may be injected by inserting a 22- to 25-gauge, 1½-inch needle from the lateral or medial aspect of the heel and directing it through the tissues of the heel pad toward the area of tenderness. About 0.5 mL of corticosteroid with 0.5 to 1 mL of lidocaine can be injected. Repeated injections in this area should be avoided because of the risk of plantar fascia rupture.⁸⁵

Metatarsophalangeal Joints

The small joints of the toes are aspirated and injected using techniques similar to those of the small joints of the hands. The metatarsophalangeal joint of the great toe is an area of particular interest because this joint is involved so often in gout. This joint may be aspirated in patients with a history suggestive of gout, even between attacks, and may yield enough fluid, sometimes to allow a diagnosis of gout to be confirmed by microscopic analysis. A small mark can be made at the joint line over the medial aspect of this joint, a 22- to 25-gauge needle can be inserted, and the area can be aspirated. Care should be taken to express the tiny amount of fluid often found in the needle hub onto a microscope slide. These joints can be injected for therapeutic benefit, usually with 0.1 to 0.25 mL of steroid.

Interdigital Neuroma

Interdigital neuroma causes pain between the metatarsal heads in the foot, usually between the second and third or third and fourth toes (Figure 54-15). Injection into this space may reduce inflammation and relieve symptoms of nerve compression between the metatarsal heads. The area is injected most easily from the dorsal aspect. The area of tenderness should be marked, a 22- to 27-gauge needle should be inserted ½ to 1 inch, and 0.25 to 0.5 mL of steroid with equal volume of anesthetic should be injected.

Figure 54-15 Injection for interdigital (Morton's) neuroma. The area is most easily injected from the dorsal aspect, usually between the metatarsal heads of the third and fourth toes. The area of tenderness is marked, the needle is inserted ½ to 1 inch, and steroid with anesthetic is injected.

CURRENT AND FUTURE TRENDS IN ARTHROCENTESIS AND JOINT INJECTION

Ultrasound-Guided Arthrocentesis and Injection

In recent years, ultrasound guidance has been the subject of numerous studies as a means to increase accuracy for needle placement for arthrocentesis and therapeutic steroid injection in joints and tendon sheaths, particularly in Europe, and is being used more often in the United States as well.¹¹⁷ One comparative study showed that ultrasound guidance increased the ability to obtain synovial fluid from joints to 97% of patients compared with 32% when using conventional techniques without ultrasound.¹¹⁸ Ultrasound has been shown to improve response to injection in many studies of painful sacroiliac joints, shoulders, fingers, and ankles compared with injections using traditional anatomic landmarks.¹¹⁹⁻¹²² However, some studies have shown no improvement in clinical effect with ultrasound guidance, possibly because many patients may benefit from periarticular steroid injection using anatomic landmarks without ultrasound guidance.^{123,124}

Ultrasound can be employed by having the area to be aspirated marked by the ultrasonographer or by having concurrent ultrasound monitoring while the needle is inserted into the joint or tendon sheath area. The latter approach has the potential to be particularly helpful in areas difficult to assess, but it is more cumbersome and requires the use of sterile components for the ultrasound machine and sterile ultrasound gel. In current practice, musculoskeletal ultrasound has the potential to improve outcomes in individual patients with pain associated with difficult-to-access joints and periarticular structures. Further studies to better define cost and clinical outcomes will be necessary to justify the more routine use of ultrasound to assist arthrocentesis and injection in clinical rheumatology practice.

Joint Irrigation

The irrigation of joints in osteoarthritis with large volumes of saline, known as *tidal irrigation*, was controversial from 1992 to 2002. On the basis of observations that some patients undergoing arthroscopy seemed to improve from the process of lavage that accompanies the procedure, subsequent studies suggested that irrigation of the joint was superior to medical management and comparable with local steroid injection.^{26,125,126} More recent studies using “sham” irrigation as control¹²⁷ and recent meta-analyses and reviews of multiple controlled trials have shown no benefit from lavage compared with placebo or added to corticosteroid in knee osteoarthritis.¹²⁸

Intra-articular Biologic Therapy

Advances in understanding of the underlying biologic processes in rheumatoid arthritis and osteoarthritis in recent years have raised hopes that intrasynovial therapy with biologic agents might have a role in the treatment of various forms of arthritis. Potential intrasynovial therapies might include agents that suppress inflammation and bone destruction (e.g., interleukin-1, interleukin-4, or tumor necrosis

factor inhibitors, adrenomedullin, bradykinin) or agents that promote cartilage growth (e.g., dehydroepiandrosterone, insulin-like growth factor, transforming growth factor- β). To date, clinical trials of intra-articular biologic therapies have been disappointing. Intra-articular tumor necrosis factor inhibitors have shown improvement that has been either inconsistent or inferior to local corticosteroid injections.^{129,130} A study of an interleukin-1 inhibitor has shown no difference compared with placebo injection in osteoarthritis.¹³¹

The ability to transfer genes to synoviocytes in vivo and ex vivo has led to speculation that the delivery of genes directly to the joints might lead to reduced inflammation and cartilage degradation in rheumatoid arthritis and osteoarthritis.

Numerous strategies have been outlined, and animal studies and early human trials of intrasynovial gene therapy using viral vectors for rheumatoid arthritis, osteoarthritis, and other diseases of the joints are ongoing.^{132,133} The role of such therapies in the future will depend on the ability to find safe and effective vectors that can deliver genetic material that persists in synovial tissues for long periods.

Antinuclear Antibodies

STANFORD L. PENG • JOSEPH E. CRAFT

KEY POINTS

The presence of antinuclear antibodies (ANAs) is characteristic of systemic lupus erythematosus (SLE), systemic sclerosis, inflammatory myositis, and Sjögren's syndrome, and is required for the diagnosis of some syndromes, such as drug-induced lupus. They may also be prognostic, such as uveitis in juvenile idiopathic arthritis or the development of overt connective tissue disease in patients with Raynaud's phenomenon or antiphospholipid antibodies. Fluorescent ANA testing is appropriate for patients in whom such diseases are clinically suspected.

Testing of individual ANA specificities should be performed only in the context of clinical signs that correlate with antibody-disease associations (e.g., anti-DNA or anti-Sm in the suspicion of SLE).

Key ANA specificities in SLE include anti-double-stranded DNA, which may correlate with renal disease and overall disease activity; anti-ribosomal P, which may correlate with neuropsychiatric manifestations and renal disease; anti-Ro/SSA and anti-La/SSB, which are associated with cutaneous and neonatal lupus; and anti-Sm, which is considered SLE specific without clear clinical disease manifestation correlation.

Key ANA specificities in systemic sclerosis include antikinetochore (antacentromere), which may correlate with CREST syndrome manifestations; anti-Scl-70 (topoisomerase I) and anti-RNA polymerase III, which are associated with diffuse cutaneous disease and pulmonary fibrosis; and anti-PM-Scl (exosome), which is found in myositis-systemic sclerosis overlap.

Key ANA specificities in inflammatory myositis include antihistidyl transfer RNA (tRNA) synthetase (e.g., Jo-1), which is associated with the poor-prognosis antisynthetase syndrome, and anti-Mi-2 (nucleosome remodeling-deacetylase complex), which is associated with dermatologic manifestations.

Key ANA specificities in Sjögren's syndrome include anti-Ro/SSA and anti-La/SSB, found in mothers of children with neonatal lupus, and antifodrin, which does not have well-documented prognostic ramifications but is observed at high frequency in the disease.

Although many ANA specificities are disease or manifestation specific, exceptions are common, confounded by the observation that many autoantibodies are present at low frequencies in healthy individuals.

ANA testing is insufficient to establish or refute diagnoses. Such results add weight to diagnoses that throughout the evaluation should rely heavily on other clinical information.

Antinuclear antibodies (ANAs) include an ever-growing diversity of autoantibodies directed against multiple intracellular antigens, classically consisting of nuclear specificities such as deoxyribonucleic acid (DNA) or small nuclear ribonucleoproteins (snRNPs).^{1,2} ANA diseases (Table 55-1) include syndromes whose patients are characterized by an unusually high prevalence of ANAs, often screened for by the fluorescent antinuclear antibody (FANA) test: systemic lupus erythematosus (SLE), systemic sclerosis (SSc), and mixed connective tissue disease (MCTD). The prevalence of ANAs in polymyositis (PM), dermatomyositis (DM), and Sjögren's syndrome (SS) has been reported to be somewhat lower than in other ANA diseases, but they are often grouped together because they share similar target antigens and therefore presumably similar causes. For decades, ANA testing has remained an important diagnostic and prognostic tool for these connective tissue diseases and has provided routine assays in the evaluation of patients with suspected rheumatic disease. However, these autoantibodies arise in a variety of infectious, inflammatory, and neoplastic diseases, as well as in normal individuals; therefore some knowledge regarding their intricacies and limitations of the assays is required for appropriate clinical application. This chapter summarizes the more common ANA specificities, outlining their history, implicated relevance to pathogenesis, methods of detection, and clinical disease associations, as well as the biology of their target autoantigens, in an effort to help guide the clinical utility of testing for these specificities.

HISTORY

KEY POINT

ANAs have evolved from clinical pathologic observations to serve as tools in the study of cellular biochemical processes.

In the first formal description of an ANA-related phenomenon in 1948, bone marrow specimens from a patient with SLE were found to contain lupus erythematosus ("LE") cells, which were subsequently found useful in the diagnosis of SLE and drug-induced lupus, as well as SS and rheumatoid arthritis (RA).³ LE cells were soon discovered to be the result of a plasma factor, autoantibody against deoxyribonucleoprotein, which opsonized and/or induced apoptosis in free-cell nuclei, resulting in antibody sensitization and phagocytosis by polymorphonuclear neutrophils. In 1957, indirect immunofluorescence allowed the development of the FANA as a more sensitive assay for SLE and related diseases.⁴ Finer distinction of autoantibody reactivities

Table 55-1 Antinuclear Antibody (ANA)-Associated Diseases and Related Conditions

Condition	Patients with ANAs (%)
Diseases for Which ANA Testing Is Helpful for Diagnosis	
Systemic lupus erythematosus	99-100
Systemic sclerosis	97
Polymyositis/Dermatomyositis	40-80
Sjögren's syndrome	48-96
Diseases in Which ANA Is Required for Diagnosis	
Drug-induced lupus	100
Mixed connective tissue disease	100
Autoimmune hepatitis	100
Diseases in Which ANA May Be Useful for Prognosis	
Juvenile idiopathic arthritis	20-50
Antiphospholipid antibody syndrome	40-50
Raynaud's phenomenon	20-60
Some Diseases for Which ANA Typically Is Not Useful	
Discoid lupus erythematosus	5-25
Fibromyalgia	15-25
Rheumatoid arthritis	30-50
Relatives of patients with autoimmune disease	5-25
Multiple sclerosis	25
Idiopathic thrombocytopenic purpura	10-30
Thyroid disease	30-50
Patients with silicone breast implants	15-25
Infectious disease	Varies widely
Malignancies	Varies widely
Healthy ("Normal") Individuals	
≥1:40	20-30
≥1:80	10-12
≥1:160	5
≥1:320	3

Adapted from Kavanaugh A, Tomar R, Reveille J, et al, American College of Pathologists: Guidelines for clinical use of the antinuclear antibody test and tests for specific autoantibodies to nuclear antigens, *Arch Pathol Lab Med* 124:71-81, 2000.

detected by FANA testing led to the description of Smith (Sm), nuclear ribonucleoprotein (nRNP), Ro/Sjögren's syndrome (SSA), and La/SSB specificities, which later gained further biologic prominence with the demonstration that their autoantigens play prominent roles in cellular homeostasis (e.g., snRNPs, targets of anti-Sm and anti-nRNP) and in regulation of premessenger RNA splicing.⁵ Subsequent investigations have revealed an ever growing array of autoantigens (Table 55-2), many of which remain largely uncharacterized. Thus, ANAs not only serve as diagnostic markers in autoimmunity but to this day have greatly aided studies on cellular biochemistry.

RELEVANCE OF ANTINUCLEAR ANTIBODIES TO DISEASE PATHOGENESIS

KEY POINT

ANAs and their respective autoantigens have been implicated in disease pathogenesis as producing directly toxic or other proinflammatory effects.

Because of the characteristic presence of these autoantibodies among the ANA diseases, ANAs have long been speculated to play a role in disease pathogenesis. Anti-DNA antibodies, for instance, have been suspected to promote inflammation in SLE nephritis via immune complex deposition, direct binding to cross-reactive glomerular antigens, and/or intracellular penetration and induction of cellular toxicity.⁶ Similarly, ribonucleoprotein antibodies such as anti-Ro/SSA, anti-La/SSB, and anti-Sm have been implicated in the pathogenesis of cutaneous or cardiac manifestations by penetrating live cells and/or binding to exposed antigens in the skin and/or the heart.^{7,8} Sera containing anti-Scl-70 (topoisomerase I) activity can induce high levels of interferon (IFN)- α , correlating with diffuse cutaneous scleroderma and lung fibrosis⁹; also, anti-Jo-1- or anti-Ro/SSA-positive sera from myositis patients have been demonstrated to induce type I IFN and/or intercellular adhesion molecule (ICAM)-1 on endothelial cells.^{10,11}

However, autoantibodies alone appear insufficient to account for disease pathogenesis. Induction of type I IFN activity by anti-Ro/SSA-containing sera, for instance, appears restricted to patients with SLE or SS, not asymptomatic individuals,¹² and surface binding of topoisomerase I may be required for a pathogenic effect of anti-Scl-70 antibodies.¹³ This may reflect additional biologic issues among or effects of the autoantigens themselves, such as novel conformations or epitopes: for instance, a proteolytically sensitive conformation of histidyl-transfer RNA synthetase (HisRS), the target of the pulmonary fibrosis-related Jo-1-specific antibody, has been described in the lung,¹⁴ and an apoptope (epitope expressed on apoptotic cells) of Ro/SSA may be specific to SLE, suggesting a unique role of apoptosis in disease pathogenesis.¹⁵ The autoantigens themselves may have unique biologic functions: 60-kD Ro/SSA, for instance, may serve as a receptor for the antiphospholipid-related β 2-glycoprotein I, and this dynamic may account for differences in Ro antibody pathogenicity.¹⁶ However, many autoantigens likely have intrinsic proinflammatory properties, such as stimulation of innate inflammation by DNA and RNA via Toll-like receptors (TLRs) 3, 7, and 9,^{17,18} or induction of smooth muscle responses by the centromere protein CENP-B via CCR3.¹⁹ Apparent remission of SLE in a patient has been correlated with loss of TLR responsiveness, antibody deficiency, and disappearance of anti-DNA, supporting such concepts.²⁰ Thus the pathogenesis of the connective tissue diseases appears to reflect a complex interplay between direct inflammatory or other biologic effects of the autoantigens and consequences of autoantibody responses.

METHODS OF DETECTION

KEY POINTS

The gold standard screening test for ANAs is the fluorescent ANA test.

Many antibody tests, including ANA screening in some laboratories, are performed via enzyme-linked immunosorbent assay (ELISA) because this method affords higher throughput testing, but this technique often results in lower specificity.

Optimal clinical interpretation of ANA tests requires knowledge of the technique(s) used in each specific case.

Table 55-2 Diagnostic Characteristics of Antinuclear Antibodies (ANAs)

Specificity	Target Autoantigen (Function)	ANA Pattern(s)	Other Tests	Primary Rheumatic Disease Associations

Immunofluorescence

The FANA provides a rapid yet highly sensitive screening method for ANA detection and remains the gold standard for clinical testing.^{21,22} Here, test sera at varying dilutions (typically serially increasing by twofold) are incubated with substrate cells, and bound antibodies are detected by fluorescein-conjugated anti-human immunoglobulin G (IgG), followed by visualization via a fluorescence microscope. Results typically are reported by two parameters—pattern and titer—with any pattern of reactivity at a titer of 1:40 or greater considered positive.²³ The former includes one or more morphologic descriptors that typically reflect localization of the respective autoantigen(s) (see Table 55-2; Figures 55-1 and 55-2). Titer is generally reported as the last dilution at which an ANA pattern is detectable, but such an assessment has been considered somewhat imprecise

and subjective, and interlaboratory standardization has not been widely instituted: Attempts to standardize the protocol have included computer-based fluorescent image quantification, subjective optical scales, and the use of standardized sera to define international units (IU/mL), although this varies by laboratory.

FANA results must always be interpreted in light of the particular substrate used by individual clinical laboratories. Many laboratories continue to use heterogeneous substrates such as rodent liver or kidney tissues; although such sections possess the advantage of eliminating interference from blood-group antibodies, heterophile antibodies, or passenger viruses, cultured cell lines such as HEp-2 cells have remained a gold standard substrate owing to their higher concentrations of nuclear and cytoplasmic antigens and standardization of use.²¹⁻²⁴ To minimize the influence of other variables, such as quality of reagents, including

fluorescein-conjugated anti-human IgG, as well as the microscope, several laboratory practices have been recommended^{23,25}: (1) performance of the test on serum stored at 4° C for up to 72 hours or at –20° C or below indefinitely; (2) use of acetone-fixed HEp-2 cells as substrate, because ethanol and methanol fixation may remove Ro/SS-A, and mouse or rat tissues contain little Ro/SS-A and do not reveal antibodies to several organelles characteristic of proliferating cells, such as centromeres (kinetochores); (3) use of IgG-specific anti-Ig fluorescein isothiocyanate (FITC) conjugates with an FITC-to-protein ratio of approximately 3.0, an antibody-to-protein ratio of 0.1 or greater, specific antibody content of 30 to 60 µg/mL, and working dilution determined by titration of reference sera with known patterns and end point titers; and (4) use of reference sera, as provided by the World Health Organization or the Centers for Disease Control and Prevention.

Enzyme-Linked Immunosorbent Assay

ELISAs provide highly sensitive and rapid techniques for the detection of autoantibodies: They are commonly used for the detection of specific ANAs, such as anti-DNA and “extractable nuclear antigen” (ENA) autoantibodies (anti-Sm, anti-Ro/SSA, anti-La/SSB, and anti-RNP), often in a “reflex” manner upon detection of a positive screening FANA test. With this technique, test sera are incubated in wells precoated with purified target antigen; bound antibodies are detected via an enzyme-conjugated anti-human immunoglobulin antibody, followed by color visualization with the appropriate enzyme substrate. The popularity of this technique has resulted from the commercial availability of ELISA kits and the ability to perform these assays on a multiplex platform, enabling large numbers of clinical specimens to be processed quickly at reasonably low cost. As a result, many laboratories also use such solid-phase immunoassays instead of FANA for the screening ANA test; however, such practice is limited by the number of displayed autoantigens (typically 8 to 10), resulting in reduced sensitivity compared with FANA.^{21,22} Conversely, because the ELISA technique can denature autoantigens, ELISAs can produce some false-positive results, and confirmation may

require further testing. Therefore recognition of the local technique used for detection of ANAs is critically important for their clinical application in diagnosis and/or prognosis.

Anti-DNA Antibody Tests

Anti-DNA antibodies warrant special consideration owing to their wide range of autoantigenic epitopes and their assay difficulties.⁶ Antibodies that recognize denatured single-stranded (ss)DNA, which are less specific for rheumatic disease, bind free purine and pyrimidine base sequences; SLE-specific antibodies that recognize native, double-stranded (ds)DNA bind the deoxyribose phosphate backbone or the rarer, conformation-dependent left-handed helical Z-form. Two methods to ensure the use of native dsDNA in anti-DNA tests include digestion with S1 nuclease, which removes overhanging ssDNA ends, and chromatography on a hydroxyapatite column, which separates single-stranded segments from dsDNA. Unfortunately, despite such efforts, native DNA may spontaneously denature, especially when bound to plastic ELISA plates; this may account for the results of several reports that revealed a relative lack of specificity of anti-dsDNA antibodies for SLE. Therefore reliable assays must ensure the integrity of dsDNA.

The Farr radioimmunoassay remains the gold standard for DNA antibody testing; it involves the binding of autoantibodies to radiolabeled dsDNA in solution. Precipitation of antibody-DNA complexes by ammonium sulfate allows quantification of the percentage of incorporated (antibody-bound) radioactive dsDNA. Normal sera typically bind a small fraction of added DNA (usually less than 20%), whereas SLE sera often bind nearly 100% of added DNA. The specificity of this assay, however, still depends on the quality of dsDNA and the removal of contaminating ssDNA. Also, because of the involvement of radioactivity, this assay is not routinely used in clinical laboratories.

In contrast, the *Crithidia* test provides an inherently reliable dsDNA substrate that is generally clinically available. In this assay, the hemoflagellate *C. luciliae* serves as a substrate for indirect immunofluorescence. Its kinetoplast, a

modified giant mitochondrion, contains a concentrated focus of stable, circularized dsDNA, without contaminating RNA or nuclear proteins, providing a sensitive and specific immunofluorescence substrate by which to establish anti-dsDNA activity. Thus together, ELISAs, *C. luciliae* immunofluorescence, and possibly Farr radioimmunoassay tests provide effective, complementary mechanisms by which anti-ssDNA and anti-dsDNA can be distinguished.

Other Assays

Several additional assays for the determination of ANA specificity have been employed in clinical and/or basic science studies.²⁶ Such techniques include immunodiffusion and counterimmunoelectrophoresis techniques, two relatively insensitive assays used in many clinical studies associating ANA specificities (especially ENAs) with disease manifestations and outcome; immunoprecipitation and immunoblot, two sensitive and specific assays predominantly confined to research settings; and enzyme inhibition assays (e.g., inhibition of topoisomerase I by anti-Scl-70, inhibition of RNA splicing by anti-snRNP), which include highly specialized techniques to characterize ANAs functionally. Such assays have not achieved widespread use in diagnostic laboratories because of their cumbersome and/or highly specialized natures.

INTERPRETATION OF THE FLUORESCENT ANTINUCLEAR ANTIBODY (FANA) TEST

KEY POINT

Although the FANA pattern and titer may provide some insight into the specific autoantigen(s) targeted, as well as the potential likelihood of connective tissue disease, such correlations should only guide, not absolutely determine, clinical decisions.

Pattern

Patterns of staining by FANA are often reported as homogeneous, speckled, or rim/peripheral when nuclear staining is present, but they may also be reported as cytoplasmic, centromere, or nucleolar, often reflecting intracellular localization of the target antigen(s) (see Table 55-2 and Figures 55-1 55-2 and 55-3). The presence of unusual patterns may be particularly helpful in appropriate clinical settings, such as the presence of a centromere pattern in a patient with features of systemic sclerosis, suggesting anticentromere antibodies, or a cytoplasmic pattern in a patient with features of myositis, suggesting anti-transfer RNA (tRNA)

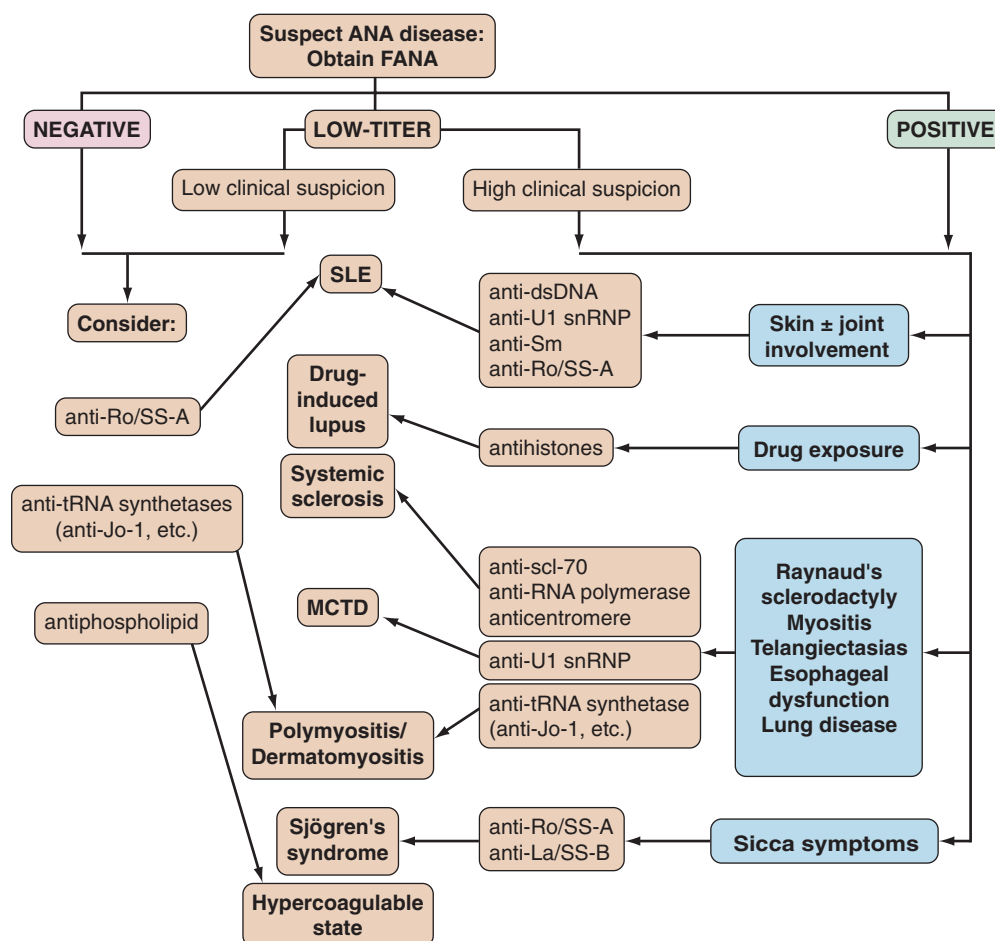

Figure 55-3 Algorithm for the use of antinuclear antibodies in the diagnosis of connective tissue disorders. See text for details. ANA, antinuclear antibody; FANA, fluorescent antinuclear antibody; MCTD, mixed connective tissue disease; SLE, systemic lupus erythematosus.

synthetase antibodies. However, the presence or absence of patterns is not always highly accurate in predicting specificity,²⁷ and non-nuclear patterns may not be reported at all by some laboratories, including rare patterns such as nuclear dot, Golgi, or antimitochondrial antibodies.^{1,28} Furthermore, the role of the FANA pattern in predicting target autoantigen specificities has been largely supplanted by widely clinically available autoantigen-specific ELISAs. As a result, the presence of any such patterns serves as evidence in an appropriate clinical setting of non-organ-specific autoimmunity, which may warrant further evaluation; however, speculation regarding the significance of a specific pattern may be worthwhile in only a select number of cases.

Titer

Although the widely accepted cutoff for FANA positivity has remained 1:40, greater clinical significance generally has been thought to correlate with higher titers.²³ Normal individuals, usually older and female persons, and relatives of persons with connective tissue diseases produce positive FANAs at a frequency sometimes exceeding 30% (see Table 55-1).^{29,30} Although these patients often possess titers of less than 1:320 with homogeneous staining patterns, many subjects possess higher titers yet remain clinically

asymptomatic for years,³¹ and occasional SLE patients may demonstrate negative FANAs; this is perhaps a more frequent observation if they possess isolated anti-Ro or anti-ssDNA antibodies and/or if the laboratory uses rat or mouse tissues.^{32,33} As a result, high- versus low-titer FANA results may not be of sufficient clinical significance to warrant differential subsequent evaluation. Rather, a positive screening FANA, of any titer, requires clinical correlation.

DISEASES ASSOCIATED WITH ANTINUCLEAR ANTIBODIES

Systemic Lupus Erythematosus

ANAs remain a hallmark of SLE: although past studies have reported FANA frequencies as low as 90%, the test is positive in more than 99% of patients with the use of current methods.³⁴ SLE often evokes autoantibodies against a seemingly endless range of antigens in many cellular locations, but most SLE autoantigens reside in the nucleus and may be broadly categorized into chromatin-associated versus ribonucleoprotein antigens (Table 55-3; also see Table 55-2), which may facilitate disease subclassification and prognosis.³⁵

Table 55-3 Antinuclear Antibodies in Systemic Lupus Erythematosus*

Antibody Specificity	Prevalence (%)	SLE Specific?	Major Disease Associations

*Shown are major antinuclear antibody specificities described in SLE, along with estimated prevalences and disease associations (bold indicates data supported by multiple studies). See text for details.

CHB, congenital heart block; dsDNA, double-stranded DNA; LE, lupus erythematosus; PCNA, proliferating cell nuclear antigen; rRNA, ribosomal RNA; SLE, systemic lupus erythematosus; snRNP, small nuclear ribonucleoprotein; TNF TRs, TNF translational regulators, including T cell intracytoplasmic antigen 1 (TIA-1) and TIA-1-related protein (TIAR).

Chromatin-Associated Antigens

Anti-DNA. Although antibodies against DNA remain one of the most widely recognized specificities in SLE, antibodies against its more physiologic forms, such as nucleosomes or chromatin, are more prevalent in and probably relevant to pathogenesis.⁶ Nonetheless, most of the clinical literature remains linked to classic anti-dsDNA antibodies (see “Anti-DNA Antibody Tests,” earlier): Many diseases exhibit anti-ssDNA activity, but only SLE sera characteristically possess high-titer anti-ds- and/or anti-Z-DNA activity, as characterized by positive Farr or *Criethidia* assays, seen in approximately 73% of patients, in contrast to low titers seen often in SS, RA, other disorders, and normal individuals.^{36,37} In SLE, anti-DNA antibodies strongly correlate with nephritis and disease activity, in contrast to other ANA specificities.^{6,36,38} In some settings, drug-induced anti-DNA antibodies are observed, as during therapy with some tumor necrosis factor (TNF) inhibitors, although they do not necessarily correlate with clinical manifestations of connective tissue disease.³⁹

Some anti-DNA antibodies may cross-react with other autoantigens, explaining correlation with other end-organ manifestations, such as the neuronal *N*-methyl-D-aspartate (NMDA) receptor or ribosomal P antigens for central nervous system disease.^{40,41} Such findings suggest that the immunologically relevant antigen for anti-DNA antibodies in fact may not be DNA. As a result, the presence of anti-DNA activity should always prompt consideration of renal disease, but the presence of anti-DNA activities does not always indicate lupus nephritis, and vice versa.

Antihistone (Nucleosome). Antihistone antibodies target the protein components of nucleosomes, the DNA-protein complexes that form the substructure of transcriptionally inactive chromatin. They are common in SLE, associate with anti-dsDNA, and are particularly characteristic of and sensitive for drug-induced lupus, where they associate with anti-ssDNA.⁴² However, they are commonly seen in other rheumatic diseases, including myositis and SSc, as well as in chronic infections, such as Epstein-Barr virus, so that clinical correlations for antihistone antibodies have not been consistent.

Other Chromatin-Associated Autoantigens. Other chromatin-associated autoantigens in SLE include several specificities also observed in other rheumatic and nonrheumatic diseases with still somewhat undefined clinical significance. For instance, autoantibodies against Ku, the catalytic subunit of the DNA-dependent protein kinase implicated in DNA repair and the V(D)J recombination, have been associated with RNA polymerase II antibodies, and one study has associated them with Raynaud's phenomenon, arthralgia, skin thickening, and esophageal reflux⁴³; however, other studies suggest that Ku subunit specificity may be more relevant, with anti-p70 antibodies correlating with features of SSc-polymyositis overlap, and anti-p80 antibodies with features of SSc or SLE.⁴⁴ Other chromatin-associated autoantigens include proliferating cell nuclear antigen (PCNA), which participates in a scaffold to facilitate DNA replication, recombination, and repair; and RNA polymerase II, which transcribes some small nuclear RNA genes and all protein-encoding genes, both of which remain of uncertain clinical correlation.

Ribonucleoproteins

Anti-Small Nuclear Ribonucleoproteins. In SLE, the best-described snRNP autoantibodies include the Sm and U1 RNP specificities, which target the RNAs or proteins of the spliceosome, a complex of RNP particles involved in premessenger RNA splicing.⁴⁵ These particles include the U1, U2, U4/U6, U5, U7, U11, and U12 snRNPs, each of which consists of its respective uridine-rich (thus U) small nuclear RNA (snRNA) and a set of polypeptides, including a common core of “Sm” polypeptides (B/B', D1, D2, D3, E, F, and G), as well as particle-specific polypeptides.⁴⁶ Anti-Sm antibodies, which target proteins of the Sm core, B/B', and one of the D polypeptides, as well as the Sm-like LSm4, appear in only 20% to 30% of SLE patients, but are considered specific for the diagnosis⁴⁷; however, their presence has only inconsistently been associated with specific disease activity and/or prognosis. In contrast, anti-U1 snRNP (nRNP, nuclear RNP, or U1 RNP) autoantibodies, which target the 70 K, A, or C polypeptides specific to U1 snRNP, occur in 30% to 40% of SLE patients but are not specific for SLE and likewise have been only variably associated with disease activity, myositis, esophageal hypomotility, Raynaud's phenomenon, leukopenia, lack of nephritis, arthralgias or arthritis, sclerodactyly, interstitial changes on chest radiographs, and central nervous system manifestations.⁴⁸ Several other snRNP antibodies have been described in SLE, often in overlap syndromes (e.g., U2-, U5-, or U7-snRNP-specific), although their clinical importance remains uncertain.⁴⁶

Anti-Ro/SSA and La/SSB. These two ribonucleoprotein particles, which are part of a macromolecular complex that predominantly processes RNA polymerase III transcripts, have been often associated with SS and the neonatal lupus syndrome, as well as with ANA-negative SLE (especially anti-Ro; see “Interpretation of the FANA,” earlier). Some but not all studies have indicated that anti-Ro may segregate among rheumatic diseases based on subunit specificities, with Ro52 without Ro60 specificities correlating with SS, while Ro60, perhaps specifically a Ro60 epitope, with or without Ro52 specificities correlating with other connective tissue diseases (CTDs), including SLE.^{15,49,50} In SLE, anti-Ro associates with several manifestations, especially skin disease (cutaneous lupus, chilblains, photosensitivity), sicca symptoms, and the neonatal lupus syndrome, including congenital heart block, anti-La, rheumatoid factor, pulmonary disease, complement (especially C4) deficiencies, thrombocytopenia, lymphopenia, and cardiac fibroelastosis^{51,52}; in comparison, anti-La correlates with late-onset SLE, secondary SS, the neonatal lupus syndrome, and protection from anti-Ro-associated nephritis.⁵³

Antiribosomes

The best-studied antiribosome antibodies in SLE, antiribosomal P protein (anti-P), target the P0, P1, and P2 proteins of the large 60S ribosome subunit. Although they occur in only a minority of patients, they are considered highly specific for SLE and particularly specific for neuropsychiatric lupus, classically psychosis⁵⁴; correlations with active disease, renal disease, liver and hematologic disease, alopecia, anti-Sm, anti-DNA, and anticardiolipin antibodies have also

been reported.⁵⁵ Other, less prevalent antiribosomal antibodies target ribosomal RNA (rRNA), such as the 28S rRNA, or other ribosomal proteins, such as the S10, L5, and L12 subunit proteins, although their clinical significance remains unclear.⁵⁶

Other Antinuclear Antibodies in Systemic Lupus Erythematosus

Many other SLE ANA specificities have been described; some are apparently quite prevalent, such as SR splicing factors,⁵⁷ proteasome,⁵⁸ the TNF translational regulator,⁵⁹ and the RNA helicase A⁶⁰ specificities. Many such specificities continue to lack clear clinical context, although preliminary analyses indicate some correlation, such as Ki-67 with sicca, or RNA with overlap syndromes. Others remain of interest because of their connection with other diseases, such as perinuclear-antineutrophil cytoplasmic antigens, topoisomerase I, and kinetochore specificities.²⁶

Systemic Sclerosis (Scleroderma)

Antinuclear antibodies against nucleolar antigens characterize the autoantibody response in SSc. Positive FANAs, sometimes speckled in appearance, appear in as much as 97% of sera, although percentages vary depending on the substrate used for detection. Unlike SLE sera, however, systemic sclerosis sera typically contain monospecific autoantibody specificities, targeting such structures as the kinetochore, topoisomerase I, or RNA polymerases (Table 55-4; also see Table 55-2).⁶¹

Antikinetochore (Centromere) and Anti-Topoisomerase I

These specificities constitute major diagnostic tools in the subclassification of SSc. Originally named *anticentromere*, antikinetochore targets at least four centromere

(kinetochore) antigens (CENPs) of the mitotic spindle apparatus that promotes chromosome separation during mitosis: CENP-B (the predominant kinetochore autoantigen), -A, -C, and -D. As such, these specificities require mitotically active cells for robust detection, accounting for some ANA-negative SSc findings (see “Interpretation of the FANA,” earlier). Their clinical significance has been extensively studied and heavily associated with Raynaud’s phenomenon and CREST, in which up to 98% of patients have antikinetochore antibodies.⁶² Other associations include limited skin involvement, mat-like telangiectasias, pulmonary or vascular disease, increased malignancy risk, and possibly reduced type I IFN responses.⁶³ In contrast, anti-topoisomerase I (Scl-70) autoantibodies, which predominantly target the catalytic region of DNA helicase topoisomerase I, generally predict diffuse cutaneous disease with proximal skin involvement, pulmonary fibrosis,⁶² longer disease duration, association with cancer, or both digital pitting scars and cardiac involvement, as well as more rapid disease activity.^{64,65} However, approximately 40% of all SSc patients lack either antibody,⁶⁶ and a minority (<1%) possess both antibodies, such that although these antibodies are clinically useful for disease classification and prognosis, they may not be used for definitive diagnoses.⁶⁷

Anti-RNA Polymerases

Anti-RNA polymerase (RNAP) antibodies, which target the eukaryotic RNA polymerases (see section on SLE: anti-RNA polymerase), associate with diffuse cutaneous involvement.⁶⁸ Although anti-RNAP II antibodies appear in other diseases, such as SLE or overlap syndrome, and may be associated with other autoantibody specificities against Ku or ribonucleoproteins, anti-RNAP I and III antibodies appear specific for SSc, in which they may be useful for the prediction of renal crisis.⁶⁹ RNAP III antibodies in particular may predict diffuse cutaneous SSc, including higher skin score, tendon friction rubs, and renal crisis.⁷⁰

Table 55-4 Antinuclear Antibodies in Systemic Sclerosis*

Antibody Specificity	Prevalence (%)	Specificity for SSc	Mutually Exclusive?†	Major Disease Associations
Kinetochore (centromere)	22-36	Relatively	Yes	CREST Diffuse cutaneous disease Pulmonary fibrosis
Topoisomerase I	22-40	Relatively	Yes	
Topoisomerase II	22			
RNA polymerases	4-23			
RNA polymerase I		Relatively	Yes	Renal crisis
RNA polymerase II		No		Overlap
RNA polymerase III		Relatively	Yes	Renal crisis, diffuse disease Lung involvement
TNF TRs	42			
B23 nuclear phosphoprotein	11

Th snoRNP (RNase MRP, 7-2 RNA)	4-16			Limited cutaneous disease Pulmonary fibrosis Myositis-SSc overlap
U11/U12 snRNP	3			
PM-Scl	2-5	No		
Sp1	?	No		
NOR 90 (hUBF)	?	No		

*Shown are major antinuclear antibody specificities described in SSc, along with estimated prevalences and disease associations (bold indicates data supported by multiple studies). Antinuclear antibody specificities whose incidences are thought to be “mutually exclusive” of each other in SSc are indicated. See text for details.

†Antibody specificity is often present exclusive of other SSc-related antibodies.

hUBF, human upstream binding factor; NOR, nucleolar organizer region; snoRNP, small nucleolar ribonucleoprotein; snRNP, small nuclear ribonucleoprotein; SSc, systemic sclerosis; TNF TRs, TNF translational regulators, including T cell intracytoplasmic antigen 1 (TIA-1) and TIA-1-related protein (TIAR).

Anti-Polymyositis-Scleroderma (PM-Scl)

Anti-PM-Scl antibodies target the PM-Scl-75 and PM-Scl-100 components of the exosome, an exoribonuclease complex that regulates ribosomal RNA.⁷¹ Responses against PM-Scl-75 alone appear more common among patients with diffuse SSc, and overlap syndromes are typically associated with responses against both components.⁷² Its presence associates with myositis-SSc overlap without SLE features: 50% of anti-PM-Scl antibody-positive patients have the overlap, and 25% of overlap patients have the antibody.⁷³ Also, anti-PM-Scl appears associated with arthritis and skin lesions of dermatomyositis, calcinosis, mechanic's hands, and eczema, and it appears to increase the incidence of muscle, tendon, and renal disease.

Other Systemic Sclerosis–Related Antinuclear Antibodies

Several other specificities have been described in SSc with possible prognostic implications, including antifibrillarin, which targets a component of the U3 small nucleolar ribonucleoprotein and may associate with diffuse disease, including internal organ or skeletal muscle involvement, or pulmonary hypertension⁷⁴; anti-topoisomerase II, which appears to associate with pulmonary hypertension, as well as localized scleroderma⁷⁵; anti-Th (Th snRNP, mitochondrial RNA processing RNase MRP), which may predict pulmonary hypertension, limited cutaneous disease, puffy fingers, small-bowel involvement, hypothyroidism, pericarditis or interstitial lung disease, or reduced arthritis or arthralgias⁷⁶; antibodies against the nuclear phosphoprotein B23, which appear to associate with pulmonary hypertension and antifibrillarin antibodies; antibodies against the RNAP II transcription activator Sp1, which seem to correlate with Raynaud's phenomenon and other signs of undifferentiated connective tissue disease; TNF translational regulator specificities, which may associate with lung involvement⁵⁹; anti-U11/U12 RNP antibodies, which appear to correlate with pulmonary fibrosis⁷⁷; and anti-nucleolar organizer region (NOR) 90 (human upstream binding factor). Other ANAs described in SSc include several specificities characteristically observed in other CTDs, such as histone, Ku, Ro, tRNA, snRNP, and ANCA, although their clinical relevance in SSc remains unclear.²⁶

Inflammatory Muscle Diseases

Inflammatory muscle diseases make up a diverse group of illnesses often characterized by autoantibody responses against cytoplasmic antigens. Although between 40% and 80% of PM/DM patients have positive ANA, as many as 90% of patients with all types of inflammatory muscle diseases have autoantibodies to cellular antigens.⁷⁸ Myositis autoantibodies are generally categorized into myositis-specific autoantibodies (MSAs), which are considered exclusive to inflammatory myositis, and those associated with overlap syndromes that include myositis (Table 55-5; also see Table 55-2).

Myositis-Specific Autoantibodies

The best-characterized MSAs include the antisynthetases, which target different aminoacyl-tRNA synthetases. Some of these antibodies target the tRNA anticodon loop, enabling them to inhibit enzymatic activity. The individual prevalences of these antibodies vary, but their clinical associations remain similar: Although PM appears more commonly with anti-Jo-1, and DM is more common with the other synthetases, these specificities together correlate with the “antisynthetase syndrome,” which includes interstitial lung disease, arthritis, Raynaud's phenomenon, mechanic's hands, hyperkeratotic lines, sclerodactyly, facial telangiectasia, calcinosis, and sicca, generally with a relatively poor prognosis.⁷⁹ Recent studies have suggested that anti-Jo-1 antibody levels may correlate with disease activity, as well as with the IFN- γ -inducible chemokines CXCL9 and CXCL10.^{80,81} Nonetheless, other disease associations have been reported, distinct from the antisynthetase syndrome. For example, one study has associated anti-threonyl-tRNA synthetase antibodies with fetal loss and severe relapsing myositis⁸²; a relatively rare activity, anti-KS, has been described against asparaginyl-tRNA synthetase in a few patients with interstitial lung disease and inflammatory arthritis or undifferentiated connective tissue disease⁸³; and PL-7 antibodies may correlate with milder muscle disease.⁸⁴

Other MSAs include specificities against Mi-2, a component of the nucleosome remodeling–deacetylase (NuRD) complex involved in chromatin remodeling and transcription regulation, which associates with dermatomyositis and dermatologic manifestations such as the “shawl” and “V” signs and ultraviolet light exposure,⁸⁵ and Mas, a UGA suppressor serine tRNA that carries selenocysteine (tRNA^[Ser|Sec]). Antibodies against the signal recognition particle, the cytoplasmic ribonucleoprotein that translocates nascent proteins across the endoplasmic reticulum, have been reported to be MSAs that associate with acute, severe, treatment-resistant disease; however, recent studies are conflicting.⁸⁶ A few recently described specificities—anti-p155 and anti-p140 (MJ, nuclear matrix protein NXP-2), anti-CADM-140, melanoma differentiation-associated gene 5 (MDA5), and transcriptional intermediary factor 1- γ (TIF1- γ)—may represent novel MSAs and may be useful in distinction of dermatomyositis subsets or cancer-associated myositis.⁸⁷⁻⁹¹

Myositis Overlap Autoantibodies

The best-described myositis overlap-associated ANAs include snRNP and PM-Scl specificities. In myositis, anti-snRNP antibodies typically target U1 snRNP, although a few anti-Sm and anti-U2 snRNP specificities have been described (see section on SLE: anti-snRNP). The former tend to associate with features of MCTD, including SLE-myositis overlap, myositis-SSc overlap, and undifferentiated features (Raynaud's phenomenon, puffy fingers, arthritis) later progressing to myositis, possibly responding to corticosteroids⁹²; anti-U2 snRNP associates with myositis and sclerodactyly, sometimes with SLE and usually without interstitial lung disease.⁴⁶ Anti-PM-Scl antibodies associate with myositis-SSc overlap without SLE features (50% of

Table 55-5 Antinuclear Antibodies in Inflammatory Muscle Diseases*

Antibody Specificity	Prevalence (%)	Disease Specificity	Major Disease Associations
Anti-tRNA synthetases			Antisynthetase syndrome

*Shown are major antinuclear antibody specificities described in inflammatory myositis, along with estimated prevalences and disease associations (bold indicates data supported by multiple studies). See text for details.

[†]Considered a myositis-specific autoantibody (MSA) despite recent findings in autoimmune hepatitis.

[‡]Often referred to as MSAs.

DM, dermatomyositis; MDA5, melanoma differentiation-associated gene 5; RNP, ribonucleoprotein; snoRNP, small nucleolar ribonucleoprotein; snRNP, small nuclear ribonucleoprotein; SUMO-1, small ubiquitin-like modifier activating enzyme subunits A and B; TIF1- γ , transcriptional intermediary factor 1- γ ; tRNA, transfer RNA.

anti-PM-Scl antibody-positive patients have overlap, and 25% of overlap patients have the antibody), and also with arthritis, DM skin lesions, calcinosis, mechanic's hands, and eczema.^{73,93} Other antibodies associated with myositis in overlap syndromes include several specificities found in other diseases, such as Ku, which is found more commonly in SLE and SSc; and U3 small nucleolar RNP (fibrillarin), which is associated with myositis in SSc, especially of the diffuse type. Several other specificities have been described in inflammatory myositis, although their clinical significance remains largely undefined (see Table 55-5).²⁶

Sjögren's Syndrome

In SS, reported incidences of positive FANAs range widely, reflecting differences in study populations and disease criteria, and depend heavily on the inclusion or exclusion of secondary, CTD-related disease, which increases the likelihood and amplitude of positive tests.²⁴ Thus, although as little as 40% ANA positivity has been reported, many studies report frequencies of 90% to 96%⁹⁴ with a diverse range of autoantibodies, including both ubiquitous (Table 55-6; see also Table 55-2) and tissue-specific reactivities such as antithyroid, gastric parietal cell, and muscarinic receptors. Such issues hinder interpretation of disease associations and disease specificities of ANAs in SS.

Of the SS ANA specificities, the best-characterized remain Ro (SSA) and La (SSB)—two nuclear RNPs involved in RNA metabolism (see section on SLE: anti-Ro/SSA and anti-La/SSB)—as well as fodrin (nonerythroid spectrin), a cytoskeletal heterodimer composed of α - and β -subunits structurally and functionally similar to erythroid spectrin. Anti-Ro antibodies appear in approximately 40% to 95% of SS patients, are associated with various extraglandular manifestations, including serologic association with anti-La and rheumatoid factor, and may result from genetically linked alternative mRNA processing of Ro.⁹⁵ Similarly, anti-La antibodies appear in as many as 87% of SS patients and are also associated with extraglandular manifestations and serologic association with anti-Ro and rheumatoid factor. Antibodies against α -fodrin have been detected in 64% to 67% of patients,⁹⁶ but they are relatively uncommon in other CTDs such as SLE. Preliminary analyses suggest some extraglandular and serologic associations. In contrast, antibodies against β -fodrin have been described in as many as 70% of patients, but clinical associations have not been reported.⁹⁷ Several other specificities have been reported in SS in a significant proportion (>3%) of patients, including antibodies against MA-1, a 200-kD protein localized to the mitotic apparatus in dividing cells (which may be identical to NuMA); p80-Coilin, an 80-kD protein associated with nuclear coiled bodies (although this antibody

Table 55-6 Antinuclear Antibodies in Sjögren's Syndrome*

Antibody Specificity	Prevalence (%)	SS Specific?	Major Disease Associations

CHB, congenital heart block; LE, lupus erythematosus; p-ANCA, peripheral antineutrophil cytoplasmic antibody; SS, Sjögren's syndrome.

might not be CTD specific); and specificities characteristically found in other rheumatic diseases such as kinetochores and perinuclear antineutrophil cytoplasmic antibodies, although their clinical importance remains uncertain (see Table 55-6).^{98,99}

Mixed Connective Tissue Disease and Overlap Syndromes

Although overlap syndromes of connective tissue disease remain matters of nosologic debate, virtually all investigators concur that ANAs are universal in these conditions.¹⁰⁰ Indeed, since the initial formal description of MCTD in 1972, the presence of anti-U1 snRNP antibodies has been consistently required for classification and/or diagnosis, with associated ANA titers typically exceeding 1:1000 and often 1:10,000.¹⁰¹ However, several investigators have noted that many such patients develop manifestations, both clinical and serologic, that allow the diagnosis of a defined connective tissue disease, such as SLE, RA, SSc, or PM/DM, and therefore the accuracy of specific clinical associations of specific ANAs in "overlap" settings is hindered by issues of disease classification. In such instances, it seems most reasonable to base the importance of individual autoantibody specificities upon their primary disease association, despite the lack of definitive, well-codified evidence (e.g., anti-topoisomerase I as predictive of eventual diffuse SSc-like skin disease or pulmonary fibrosis, or anti-dsDNA for lupus-like glomerulonephritis).

Other Conditions

In contrast to traditional ANA diseases, the presence of a positive ANA in other diseases remains largely unhelpful for diagnosis, although in Raynaud's phenomenon (RP), juvenile rheumatoid arthritis (JRA), and antiphospholipid antibody syndrome (APS), it can aid prognosis (see Table 55-1). In RP, a positive result increases the likelihood—from 19% to 30%—of the development of a systemic rheumatic disease, including SLE, RA, and SSc, and a negative result decreases the likelihood to approximately 7%, which is often helpful for patient reassurance.^{102,103} In JRA, a positive ANA may predict the development of uveitis^{104,105}; in

APS, it may predict the development or the presence of underlying SLE.¹⁰⁶ Other conditions in which ANAs have been found include other rheumatic diseases such as the vasculitides or sarcoidosis; autoimmune diseases such as multiple sclerosis or inflammatory bowel disease; and an ever-growing list of additional conditions such as dermatologic, infectious, psychiatric, neurologic, and cardiovascular diseases. In general, studies describing such associations lack comprehensive analyses regarding the significance of ANAs, such that use of the ANA outside of the rheumatic diagnoses indicated here (see Table 55-1) remains largely exploratory.

CONCLUSION: CLINICAL UTILITY OF ANTINUCLEAR ANTIBODY TESTING

The ANAs encompass an ever-widening range of nuclear, nucleolar, and cytoplasmic autoantigen specificities. Within the ANA diseases—including SLE, SSc, PM/DM, SS, and MCTD—many autoantibodies possess unique rheumatologic associations, but the specificity of these associations has diminished as the sensitivity of clinical studies has increased the detection of these specificities in both rheumatic and nonrheumatic diseases. Consequently, tests for ANAs can greatly facilitate the clinical evaluation of patients in the context of their particular disease associations, but these studies retain only an adjunct role in rheumatologic diagnosis.

Figure 55-3 describes an algorithm for the rheumatologic evaluation of a patient for ANAs. In most clinical laboratories, the FANA serves as a screening test, and a positive result often prompts "cascade" testing by the laboratory, the ordering physician, or both with ELISAs or other assays for specific autoantibody specificities, such as anti-dsDNA, anti-Ro/SSA, anti-La/SSB, anti-RNP, and anti-Sm.^{23,24} A negative or low-titer FANA in the setting of low clinical suspicion of rheumatic disease usually indicates the absence of significant ANAs and argues against diagnosis of one of the ANA diseases (see Table 55-1)¹⁰⁷; however, if the clinical picture strongly suggests connective tissue disease,

further investigation may involve specific assays for antigens that are often FANA negative, such as Ro, Jo-1, or phospholipids. On the other hand, because some specific ANAs possess diagnostic significance, positive FANA results usually warrant follow-up with specialized assays—but only in the setting of strong clinical suspicion, because the positive predictive value of an ANA in the absence of other clinical signs of CTD is low, in part because ANAs may precede clinical disease by many years,¹⁰⁸ and in part because of the relatively high incidence of ANA in normal individuals.²⁹ Thus, if SLE features are present, further work may focus on anti-DNA, anti-Sm, anti-U1 snRNP, and anti-Ro antibodies. Similarly, if MCTD, SS, SSc, or polymyositis is suspected, the serum may be tested, respectively, for anti-U1 snRNP; anti-Ro or anti-La; anti-topoisomerase I, anticentromere, or antinucleoli; or anti-tRNA synthetases. If these tests are negative in the setting of high clinical suspicion, repeat testing at a later date may be warranted, because titers of such autoantibodies can fluctuate over time, irrespective of the disease course.¹⁰⁹ Positive results with these more specialized assays do not alone signify specific diseases, but rather add weight to diagnoses that should throughout the evaluation rely heavily on other clinical information. Indeed, many clinical and research studies upon which autoantibody-disease associations have been developed often utilized highly refined detection methods, such as immunoprecipitation and immunoblot, which often are unavailable in routine clinical laboratory testing. Thus, the relevance of many antibody test results in specific clinical settings continues to require careful, individualized interpretation by the referring physician.

KEY POINTS

Autoantibodies in rheumatoid arthritis (RA) are important tools for diagnosis and for defining important pathogenic pathways in this disease.

Rheumatoid factors (RFs) are autoantibodies that recognize the Fc portion of immunoglobulin G molecules and were the first autoantibodies described in RA.

RFs have numerous causes in addition to RA and therefore have limited specificity for RA.

Autoantibodies targeting citrullinated proteins are hallmarks of the immune response in RA.

The anticyclic citrullinated peptide (anti-CCP) assay broadly detects antibodies against citrullinated proteins (ACPAs) and has high specificity and excellent sensitivity in RA.

Anti-CCP/ACPAs precede the onset of clinical RA and are associated with more severe disease, making them useful as diagnostic and prognostic tools.

Peptidylarginine deiminase (PAD) enzymes, which catalyze the conversion of peptidylarginine to peptidylcitrulline, play important roles in generating autoantigens in RA.

Genetic factors such as “shared epitope” HLA-DR alleles appear to interact with environmental factors such as smoking and infection to initiate and drive autoimmunity in RA.

Autoantibodies have proven to be useful tools for diagnosis and prediction in the autoimmune rheumatic diseases. Emerging data in several autoimmune rheumatic diseases have demonstrated that clinical evolution of disease from preclinical phase to overt clinical disease is marked by a change in the specificity of the immune response, with autoantibodies directed against distinct antigenic targets at different disease phases. Although many other autoimmune rheumatic diseases have traditionally been marked by highly phenotype-specific autoantibody responses (e.g., anti-dsDNA antibodies in systemic lupus erythematosus [SLE], high-titer anti-topoisomerase-1 antibodies in diffuse scleroderma), the discovery of highly specific autoantibody markers of rheumatoid arthritis (RA) lagged significantly behind these other diseases. During the past decade, there has been enormous progress in this area, largely fueled by the discovery that citrullinated proteins are specific targets of autoantibodies in RA. This chapter reviews the autoantibodies in RA, with emphasis on both rheumatoid factors (RFs) and anticitrullinated protein autoantibodies (ACPAs). The implications of these specificities for diag-

Autoantibodies in Rheumatoid Arthritis

FELIPE ANDRADE • ERIKA DARRAH • ANTONY ROSEN

nosis and prediction of outcome, as well as for understanding pathogenic events in the disease, are highlighted.

RHEUMATOID FACTOR

The earliest assays (later called the Rose-Waaler agglutination test), which suggested the existence of autoantibodies in RA, were developed in the early 1940s. At this time serum from RA patients was shown to cause agglutination of sheep blood cells, which had been sensitized with subagglutinating doses of rabbit anti-sheep erythrocyte antibodies.^{1,2} These assays were later shown to detect immunoglobulin M (IgM) antibodies from RA patients that recognized the Fc portion of IgG³ (Table 56-1). Numerous modifications of the agglutination assay evolved, particularly the use of IgG-coated latex beads instead of sheep erythrocytes.^{4,5} Subsequent developments established RF assays in radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), and nephelometry formats, with increased convenience but similar performance in terms of sensitivity and specificity. RFs may be positive in healthy controls (1% in younger individuals, up to 5% in individuals older than 70 years) and in patients with numerous other non-RA diseases (including other rheumatic diseases such as Sjögren's syndrome and cryoglobulinemia), as well as chronic infections (see Table 56-1).⁶⁻⁸ The pretest probability of diagnosing RA therefore greatly influences the performance of the RF test, with sensitivities and specificities both in the 50% to 90% range, depending on the patient groups studied.^{9,10} The existence of IgG and IgA RFs and evidence of somatic hypermutation have suggested that some RFs in RA are T cell dependent.^{11,12} Although there have been studies suggesting that IgG and IgA RFs increase the specificity of RFs for RA,¹³ a recent meta-analysis showed that assays of the different RF isotypes performed similarly in terms of sensitivity and specificity and therefore do not add much over standard RF assays.¹⁴

Importantly, patients with RA also vary in terms of timing of RF appearance, with RFs preceding symptomatic disease in a significant subpopulation¹⁵⁻¹⁸ and following disease onset with variable kinetics in other patients. Indeed, the earlier onset of RF in patients with RA has been associated with more severe disease, highlighting a possible contribution of these antibodies to amplification.¹⁹ The observation that RF only appears after disease onset in some patients suggests that it may mark distinct, sequential events in pathogenesis that are close together in the subgroup in whom RF occurs early or are separated in time in patients in whom RF follows symptoms. The possible mechanisms whereby RF may play an amplifying role are numerous and include amplification of antigen capture, signaling, and effector functions, among others.²⁰

Table 56-1 Citrullinated and Noncitrullinated Autoantigens in Rheumatoid Arthritis (RA)

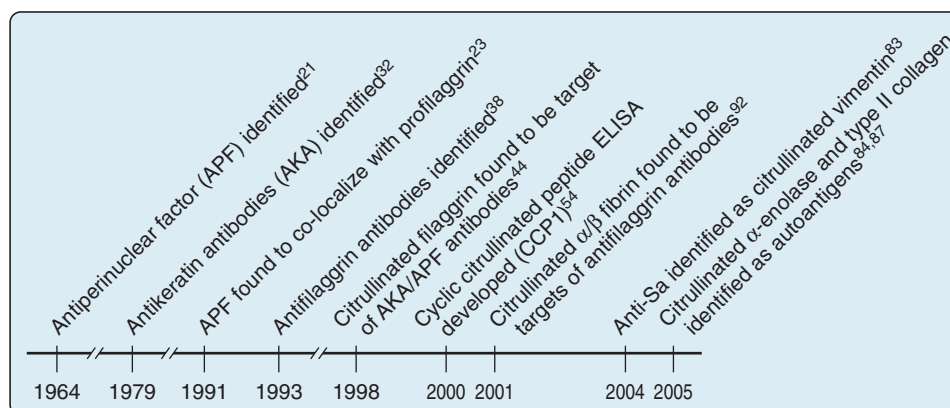

Autoantigen	Size (kD)	Function (Location)	Cell/Tissue Type	Epitopes	Prevalence of Autoantibodies
Citrullinated					
Aldolase	160	Glycolytic enzyme (cytosol)	Widely expressed		
Calreticulin	55	Ca ²⁺ sensor/chaperone (endoplasmic reticulum)	Widely expressed		
Collagen type II	≈140	Structural component (extracellular)	Cartilage	C1II (aa 359-369) J1 (aa 551-564) U1 (aa 494-504)	15%-25% to unmodified antigen 40% to citrullinated C1II
α-Enolase	49	Glycolytic enzyme (cytosol)	Widely expressed	CEP-1 (aa 5-21; cit 9 and 15) α/β Chains	50% of CCP2-positive patients 60%-66%
Fibrinogen/fibrin	340	Coagulation cascade (extracellular)	Plasma RA synovium		
FUSE-BP 1/2	71/78	mRNA Trafficking (nucleus)	Widely expressed		
HSP-60	60	Heat shock protein (cytosol, mitochondria)	Widely expressed		
PAD4	74	Citrullination enzyme (nucleus)	Granulocytes, monocytes	aa 1-120	30%-40%
Vimentin (Sa)	57	Intermediate filament (cytoskeleton)	Spleen, placenta, RA synovium		20%-25% Early RA, 47% established RA
Noncitrullinated					
G6PI	63	Glycolytic enzyme (cytosol)	Widely expressed		12%-29%
hnRNP-A2 (RA33)3	33	mRNA Processing (nucleus)	Widely expressed		35%
IgG (Fc)	≈50	Antibody (extracellular)	Serum/plasma		50%-90%

ANTICITRULLINATED PROTEIN AUTOANTIBODIES

Antikeratin Antibodies and Antiperinuclear Factor in Rheumatoid Arthritis

Although RFs have been clinically useful in diagnosis of RA, particularly in cases in whom the index of clinical suspicion is high, these autoantibodies have suffered from two shortcomings: (1) their lack of specificity for RA and (2) unclear kinetic and mechanistic connection to pathogenesis. Defining additional autoantibodies specific for RA has therefore been a major priority. A significant discovery in this regard was made initially by Nienhuis and Mandema in 1964²¹ (Figure 56-1). They recognized an autoantibody that stained keratohyalin granules surrounding the nucleus in cells of human buccal mucosa, which they called antiperinuclear factor (APF). These APF antibodies were found in 49% to 91% of RA patients²¹⁻²⁵; they have reported

specificities of 73% to 99%.^{21,24-27} The assay was difficult to standardize because not every donor of buccal mucosal cells demonstrated the staining pattern.²⁸⁻³¹ The assay therefore did not find its way into routine clinical practice, but the specificity for RA suggested that the assay might be reporting on a potentially important pathogenic pathway. A second research group subsequently demonstrated that RA sera recognized antigens in the stratified squamous layer of esophageal epithelium—a staining pattern that they termed antikeratin antibodies (AKAs).³² Subsequent iterations of this assay used other forms of stratified squamous epithelium including human skin.³³ Although this AKA assay also had good specificity properties, it was of limited sensitivity³⁴⁻³⁷ and not particularly convenient or easy to standardize. Neither assay therefore was broadly used in the clinical diagnostic arena. Like the LE cell in SLE, however, the assays provided a framework for antigen discovery that would later lead to highly specific and convenient tools for RA diagnosis and classification.

**Figure 56-1** A timeline of the discovery of anticitrullinated peptide antibodies. ELISA, enzyme-linked immunosorbent assay.

Discovery of Autoantibodies That Recognize Peptidylcitrulline

The initial discovery of antibodies in RA patients, which recognized keratinized squamous epithelium, prompted studies to define the target of these antibodies. It was initially shown that APF only stained a fully differentiated squamous epithelial layer and that APF staining was identical to the pattern produced by a monoclonal antibody specific for human (pro)filaggrin in indirect immunofluorescence of permeabilized squamous epithelial cells²³ (see [Figure 56-1](#)). Although the antigen could not be definitively identified using this co-localization alone, it suggested that a differentiation state might affect antigen recognition. Subsequently, RA sera were shown to recognize a 40-kD protein extracted from human epidermis; this was identified as a neutral/acidic isoform of filaggrin.³⁸ IgG from RA sera affinity purified against the 40-kD filaggrin protein was reactive in both the APF and AKA tests, demonstrating that these autoantibodies were similar or identical.³⁹ Filaggrin (filament-aggregating protein) is produced during the late stages of terminal differentiation of epithelial cells. It is synthesized as a heavily phosphorylated precursor protein (profilaggrin) that consists of 10 to 12 filaggrin repeats.⁴⁰ Profilaggrin is deposited in granules, and it is released by proteolytic cleavage during differentiation of the cells, by proteases that remain to be fully defined. Coincident with cleavage, the protein is dephosphorylated and a significant proportion ($\approx 20\%$) of the arginine residues are deiminated (i.e., converted to citrulline),^{41,42} a posttranslational modification mediated by the peptidylarginine deiminase (PAD) enzymes (see later).⁴³ Because RA sera appeared to specifically target the neutral isoform of filaggrin (which is present and citrullinated in fully differentiated squamous epithelia), Schellekens and colleagues⁴⁴ addressed whether RA sera positive in the AKA/APF assays specifically recognized citrullinated peptides. Thus regions within the deduced amino acid sequence of human profilaggrin with a high antigenicity index and the largest number of arginine residues were selected to generate synthetic peptides, where arginine residues were substituted with citrulline. Using these citrullinated peptides, Schellekens and colleagues demonstrated that AKA/APF antibodies are directed against citrullinated filaggrin. It is important to highlight that antibodies against citrullinated proteins in RA do not recognize free citrulline but do recognize citrulline residues (i.e., peptidylcitrullines) within the context of peptides or protein sequences.

These initial studies became the basis for the truly major discovery that protein sequences containing citrulline residues are one of the most prominent targets for autoantibodies in RA. However, because the epidermis is not a target of rheumatoid inflammation and there is no evidence that (pro) filaggrin is expressed in articular tissues, this molecule cannot be the autoantigen that drives the AKA/APF response in the joint. The facts that anticitrullinated filaggrin antibodies were enriched in synovial tissue compared with the serum or synovial fluid⁴⁵ and that these antibodies are synthesized locally by plasmacytes within the rheumatoid pannus⁴⁶ strongly suggest that anticitrullinated filaggrin cross-reacts with an antigen enriched in the RA joint/

synovial tissue. Because citrullination is a frequent event in different tissues,⁴⁷⁻⁵¹ great caution must be exercised when attempting to ascribe a primary role for a specific antigen in driving the anti-peptidylcitrulline antibody response. The relevance of filaggrin in RA is therefore largely historical but unlikely of pathogenic relevance. Instead, its conformation and high content of citrulline residues make it an excellent surrogate with which to detect antibodies against citrullinated molecules. Many other citrullinated autoantigens found in the rheumatoid joint, which are currently being characterized, are much more likely to be of pathogenic relevance (see later).

Anti-CCP Antibodies: Clinical Relevance

In the initial characterization of AKA/APF antibodies, Schellekens and colleagues⁴⁴ used a single C-terminal peptide derived from filaggrin (amino acids 306 to 324) to generate nine variants in which five arginine residues were changed to citrullines, either individually or in pairs, and these peptides were all assayed by ELISA. Interestingly, although the peptides were almost identical (the only difference being that the citrulline residues had different positions within the peptide), there were remarkable differences in the serum reactivity patterns toward each peptide (from 20% to 48% positivity), suggesting that although citrullination plays a critical role in antigen recognition by AKA/APF antibodies, the modification per se is not the only determinant that confers antibody binding. Instead, the data suggested that AKA/APF represent a pool of antibodies that recognize citrulline residues depending on the context of their surrounding amino acids. Indeed, when data from all peptides were pooled, the sensitivity increased to as much as 76%.⁴⁴ Because peptides often adopt a β -turn conformation within the antibody-peptide complex⁵² and cysteine-bridged cyclic peptides have been shown to mimic the β -turn structure of the original antigenic determinant and can bind with enhanced affinity to antibodies,⁵³ Schellekens and colleagues⁵⁴ engineered a cyclic peptide (substituting the terminal serine residues with cysteines and cyclizing the peptide through the formation of a disulfide bond) to which ACPAs reacted with higher affinity (see [Figure 56-1](#)). Using this cyclic citrullinated peptide (later named CCP1) and its linear counterpart, it was demonstrated that the cyclic structure increased the sensitivity of the assay (68% vs. 49%, without affecting specificity),^{44,54} although it was still less sensitive than the assays using the combination of linear peptides (i.e., 76% vs. 68%).⁴⁴ Nevertheless, CCP1 became the antigen for the first generation of ELISAs designed to detect antibodies against citrullinated autoantigens. To improve the CCP1 test, libraries of citrullinated peptides were used to construct the second-generation anti-CCP assay (CCP2), which was broadly adopted for clinical use.^{55,56} In 2005 a third generation of anti-CCP (CCP3) was made available for the laboratory diagnosis of RA. These assays have been reported to recognize additional citrullinated epitopes that are not identifiable with the second-generation CCP assays. In studies directly comparing second- and third-generation anti-CCP assays, the assays performed similarly,^{57,58} with a slightly increased sensitivity of CCP3 in some studies (e.g., sensi-

Figure 56-2 Protein citrullination as a hub in rheumatoid arthritis (RA) pathogenesis. CCP, cyclic citrullinated peptide; PAD, peptidylarginine deiminase; TNF, tumor necrosis factor.

tivities of 82.9% vs. 78.6% for CCP2, with specificities in the 93% to 94% range).⁵⁸

The clinical importance of anti-CCP antibody tests in RA stems from several favorable features (Figure 56-2): (1) *Anti-CCP antibodies have high specificity for the diagnosis of RA.* In systematic reviews and meta-analyses, anti-CCP antibody positivity has been shown to be as sensitive as, but more specific than, RF in distinguishing RA from other forms of inflammatory arthritis.¹⁴ (2) *The presence of anti-CCP autoantibodies is an important predictor for development of RA.* More than 90% of the patients with undifferentiated arthritis who tested positive for anti-CCP develop RA within 3 years, in contrast to only 25% of the anti-CCP negative patients.⁵⁹ (3) *Anti-CCP positivity has been associated with a more severe and destructive disease course, although the independent role of the antibody in comparison with RF has not yet been confirmed.* Some investigators have shown that both RF and anti-CCP antibodies are independent predictors of severity, whereas others have shown that anti-CCP antibodies rather than RF are the better predictor of radiographic progression,⁶⁰⁻⁶⁷ particularly in those patients who were seronegative for RF.⁶⁷

The early and accurate diagnosis of RA, together with early, adequate use of disease-modifying antirheumatic drugs, decreases accrual of joint damage in RA. Because anti-CCP antibodies are a marker of disease severity and are detectable early in the disease course, they are powerful tools to classify patients with early inflammatory arthritis who will benefit from treatment.⁶⁸⁻⁷⁰

Kinetics of Appearance of Anti-CCP Antibodies in Rheumatoid Arthritis

Recent studies have demonstrated that autoantibodies may precede onset of clinical disease in both tissue-specific and systemic autoimmune diseases.^{17,71-77} Defining events before clinical onset is challenging, and several different study designs have been employed to define the appearance of autoantibodies and their relationship with disease. The two general categories include (1) stored blood samples collected before disease onset (blood banks or military cohorts); (2) prospective studies examining emergence of autoantibodies and disease in high-risk individuals (often relatives

of affected individuals).⁷⁸ In RA, the former approach has clearly shown that autoantibodies precede RA in many individuals who subsequently develop seropositive RA, often by 2 to 6 years.^{76,77,79,80} In several studies, 20% to 60% of RA patients were RF positive before diagnosis and 30% to 60% of patients were positive for anti-CCP.^{76,77,79,80} With one exception,⁸⁰ the prevalence of anti-CCP before diagnosis was almost twice as high as RF. Interestingly, although RF remained present consistently, anti-CCP could vary over time, even disappearing in some individuals. In one study, preclinical anti-CCP positivity was strongly associated with the development of erosive RA (odds ratio = 4.64; 95% confidence interval, 1.71 to 12.63; $P < 0.01$), whereas RF was not ($P = 0.60$).⁸⁰ Together, these data highlight that the development of autoimmunity against citrullinated antigens is often asymptomatic and generally precedes the onset of clinical disease. This presymptomatic phase is potentially of great importance because it may identify individuals in whom important precursor conditions for the subsequent development of RA have been satisfied. The subsequent events that convert this RA precursor into a chronic, self-sustaining process are not yet known, but defining them is of great importance.

Anticitrullinated Protein Autoantibodies

Defining the primary antigen(s) that drive the generation of ACPAs has important implications in terms of RA etiology and pathogenesis. AKA/APF were the first ACPAs to be characterized, and they recognized citrullinated forms of filaggrin or its precursor profilaggrin.^{44,81}

To date, several different approaches have been used to identify potential ACPA targets in RA. Although these approaches all use protein sequencing to identify autoantigens detected by ACPAs using immunoblotting assays, they vary in terms of the source of the antigens. Thus in addition to RA pannus, identification of citrullinated autoantigens has been extended to rheumatoid synovial fluid, as well as to cell lysates in which purified PADs have been used to generate in vitro citrullinated proteins. Using these approaches, several citrullinated autoantigen candidates have been identified. These include vimentin^{82,83}; fibronectin; α -enolase, elongation factor-1 α , and adenylyl cyclase-

associated protein-1⁸⁴; F-actin capping protein α -1-subunit, asporin, cathepsin D, beta-actin, histamine receptor, protein disulfide-isomerase, ER60 precursor, and mitochondrial aldehyde dehydrogenase⁸⁵; collagen types I⁸⁶ and II⁸⁷; eukaryotic translation initiation factor-4G1⁸⁸; aldolase, phosphoglycerate kinase-1 (PGK1), calreticulin, HSP60, and the far upstream element binding proteins (FUSE-BP) 1 and 2⁸⁹; and PAD4.⁹⁰ Interestingly, some of these molecules (e.g., vimentin, α -enolase, collagen type II, HSP60, aldolase, calreticulin, and PAD4) had been previously identified as autoantigens in RA, before recognizing that protein citrullination played a role in their recognition by autoantibodies^{84,91} (see Table 56-1). Although RA sera containing ACPAs may recognize both the native and the citrullinated forms of the antigen, the modified form is usually preferentially recognized. Among the citrullinated candidate antigens present in the joint, the best characterized clinically and pathogenically are fibrin(ogen), vimentin, collagen type II, and α -enolase. These antibodies are each dealt with briefly as follows.

Antibodies Recognizing Citrullinated Fibrinogen

The first local targets for ACPAs identified in RA synovial tissue were the citrullinated forms of the α and β chains of fibrin(ogen)⁹² (see Table 56-1). Using protein extracts from rheumatoid synovial membranes and affinity-purified anti-citrullinated flaggrin antibodies, Masson-Bessière and colleagues⁹² identified for the first time that RA synovial tissue contains several citrullinated proteins and defined among them two proteins that were specifically targeted by anti-citrullinated flaggrin antibodies. By amino-terminal sequencing the proteins were identified as the α - and β -chains of fibrin (although indeed, these sequences cannot allow distinguishing between fibrin and its precursor fibrinogen).⁹² Fibrin is the cleavage product of fibrinogen, a molecule that is processed by thrombin in the final steps of the coagulation cascade. Fibrinogen is a dimeric glycoprotein, with each monomer composed of three polypeptides: the A α (610 residues), the B β (461 residues), and the γ (411 residues). Thrombin cleaves fibrinogen at A α Arg-16 and at B β Arg-14, which result in the release of fibrinopeptides A and B, and exposure of the E_A and E_B polymerization sites. Cleavage of fibrinogen leads to formation of fibrin monomers that spontaneously polymerize to form a fibrin clot. Interestingly, fibrin deposition is usual during tissue inflammation and the presence of fibrin has long been known to be particularly abundant in rheumatoid synovial tissue,⁹³ likely as a result of an altered balance between coagulation and fibrinolysis.^{93,94} Because circulating fibrinogen is not citrullinated, the presence of citrullinated fibrin in the rheumatoid synovium strongly suggested that after fibrin deposition, citrullination likely occurs *in situ* through the activity of locally expressed PAD. This proposal (i.e., that the joint is the site for autoantigen citrullination in RA) has been further supported and extended to many other citrullinated autoantigens in RA.⁹⁵ Citrullinated fibrinogen antibodies are among the most frequent ACPAs found in patients with RA (\approx 60% to 66%).⁹⁶⁻⁹⁸ In total, 54 of the 81 arginines (66%) in human fibrinogen have been found to be susceptible to citrullination.⁹⁹⁻¹⁰¹ Using linear citrullinated

peptides, major citrullinated epitope regions have been identified in this molecule, with some overlap among studies, but also with clear differences.^{101,102} Although some of these peptides have been used to detect ACPAs against citrullinated fibrinogen, whole citrullinated fibrinogen is the more widely used antigen in these assays.⁹⁶⁻⁹⁸

Antibodies Recognizing Citrullinated Vimentin

The Sa autoantigen (named after a patient, Mrs Sa ...) was described between 1992 and 1994 as an approximately 50-kD band detected by immunoblotting using RA sera against normal human spleen, placenta, and rheumatoid synovial extracts.^{103,104} Subsequent studies confirmed that anti-Sa antibodies are highly specific for RA (\approx 95%), with a sensitivity that varies with the stage of the disease tested, ranging from 20% to 25% in early RA cohorts and 47% in patients with more established disease.¹⁰⁴⁻¹⁰⁶ However, although anti-Sa autoantibodies were shown to be present early in the disease and to be markers of an aggressive and destructive form of RA,¹⁰⁵ their diagnostic value was limited because of the challenge in standardizing and hence marketing the assay. Further attempts to purify the Sa antigen from placenta identified vimentin as the elusive candidate,^{83,107} a molecule that was known to be citrullinated in activated macrophages¹⁰⁸ (see Table 56-1). Vimentin is an intermediate filament protein important in the dynamic organization of the cytoskeleton, with a vital function in organelle transport, cell migration, and proliferation.^{109,110} Vimentin filaments are also involved in the regulation of mechanical stress between chondrocytes and the surrounding matrix tissues. Its assembly and disassembly are regulated by phosphorylation and potentially by deimination.¹¹¹ During macrophage apoptosis, vimentin is citrullinated and this process has been suggested to be involved in filament disassembly.¹⁰⁸ Whether citrullination of vimentin is involved in other physiologic processes is unknown. The frequency of anti-citrullinated vimentin antibodies in RA varies widely depending on the study and the antigen used for detection. Initially, partially purified preparation of placental Sa antigen was used to detect anti-Sa antibodies by Western blot. For this assay, the sensitivity varies from 22% in patients with early arthritis to 47% in patients with established disease.¹⁰⁴⁻¹⁰⁶ More recently, Bang and colleagues¹¹² identified various citrullinated and mutated isoforms of vimentin in synovial fluid of RA patients and suggested that mutations in vimentin may result from oxidative stress-induced DNA damage in RA synovium. Protein sequence data demonstrated that the vimentin isoforms contained certain amino acid mutations and modifications, in particular mutations of glycine residues into arginine residues at positions 16, 59, 145, and 147, allowing novel citrullination in the mutated residues 145 and 147. Using this molecule (named mutated citrullinated vimentin or MCV) in ELISA assays, the sensitivity of ACPAs (presumably against citrullinated vimentin) increased to 54% in patients with early synovitis who developed RA¹¹³ and as high as 92% in patients with early RA (<2 years' duration) versus 81% in patients with established RA (>2 years' duration).¹¹⁴ The overall sensitivity and specificity profile of this assay has been noted to be the best among available ACPAs (i.e., around 84% and 87%).¹¹⁵

Antibodies Recognizing Citrullinated Enolase

Antibodies against the immunodominant epitope of α -enolase, citrullinated α -enolase peptide 1 (CEP-1),¹¹⁶ occur in approximately half of anti-CCP2-positive patients¹¹⁷ (see Table 56-1). Enolase, also known as *phosphopyruvate dehydratase*, is a metalloenzyme responsible for the catalysis of the conversion of 2-phosphoglycerate to phosphoenolpyruvate, the penultimate step of glycolysis. It is also involved in various processes including hypoxia tolerance, growth control, and fibrinolysis.¹¹⁸ There are three subunits of enolase, α , β , and γ , each encoded by a separate gene that can combine to form five different isoenzymes: $\alpha\alpha$, $\alpha\beta$, $\alpha\gamma$, $\beta\beta$, and $\gamma\gamma$. Three of these isoenzymes (all homodimers) are more commonly found in adult human cells than the others: $\alpha\alpha$ or non-neuronal enolase (also known as enolase 1) is found in a variety of tissues including liver, brain, kidney, spleen, and adipose; $\beta\beta$ or muscle-specific enolase (enolase 3); and $\gamma\gamma$ or neuron-specific enolase (enolase 2). Citrullinated α -enolase is a target for ACPAs.⁸⁴ However, whether this modification plays a role in the physiologic function of the enzyme or whether its citrullination only occurs under pathologic conditions (e.g., during cell death, either intracellularly or extracellularly) remains unclear. Using cyclic citrullinated α -enolase peptides covering 15 out of 17 arginine residues present in human α -enolase, CEP-1 was identified as the immunodominant B-cell epitope.¹¹⁶ This region comprised amino acids 5 to 21 of α -enolase, with arginine-9 and arginine-15 replaced by citrulline. Although antibodies against CEP-1 have not shown a better diagnostic or prognostic value than anti-CCP2,¹¹⁷ α -enolase has gained special attention as a potential target for disease initiation (see later).

Antibodies Recognizing Citrullinated Collagen Type II

Type II collagen is the predominant collagenous component of cartilage and is an autoantigen implicated in disease initiation in RA (see Table 56-1). Immunization with collagen type II is associated with development of autoimmune arthritis in several species, and the epitope-specific recognition of type II collagen by RA antibodies is shared by antibodies that are arthritogenic in collagen-induced arthritis (CIA) in the mouse.¹¹⁹ The antibody response to collagen type II is predominantly directed toward conformational triple-helical structures, and the identification of relevant B-cell epitopes has required the construction of recombinant triple-helical proteins and synthetic triple-helical peptides.¹²⁰ The major B-cell epitopes on triple-helical collagen type II identified including C1 III (amino acids 359 to 369), J1 (amino acids 551 to 564), and U1 (amino acids 494 to 504) seem to share a common motif, comprising an arginine-glycine-hydrophobic amino acid motif. The observation that arginines occur in most of the collagen type II epitopes has raised the possibility that these may be citrullinated by PADs and that autoantibodies might bind specifically to the citrullinated forms. Indeed, using triple-helical molecules with the C1 epitope citrullinated, the diagnostic sensitivity for RA was 40%,^{87,98} compared with only 15% to 25% using the unmodified antigen.^{87,121-124}

Citrullinated Antigen Generation in Rheumatoid Arthritis

Peptidylarginine Deiminase Enzymes

The PADs, which are deiminating enzymes that hydrolyze guanidinium side chains in peptidylarginine to yield peptidylcitrulline and ammonia, belong to a larger group of guanidino-modifying enzymes called the *amidinotransferase* (AT) *superfamily*.^{125,126} Additional members of this superfamily include (1) the arginine deiminases (ADIs), enzymes found in both prokaryotes and the primitive eukaryote *Giardia intestinalis*, that act on nonpeptidyl arginine and that are involved in energy production; (2) the dimethylarginine dimethylaminohydrolases (DDAHs), enzymes found in both bacteria and mammals that convert nonpeptidyl methylarginines into citrulline; (3) the ATs, enzymes involved in both creatine and streptomycin biosynthesis; and (4) the dihydrolases, bacterial enzymes involved in arginine catabolism that catalyze two successive hydrolytic steps.¹²⁶ Whereas most superfamily members act on nonpeptidyl amino acids, PADs are highly specific for peptidylarginine residues and require at least one additional residue N-terminal to the site of modification.¹²⁷ Although the chemical reaction catalyzed by PAD enzymes is officially called *peptidylarginine deimination*, the term *citrullination* is more generally used. PAD and PAD-like enzymes are present in numerous species, from bacteria to humans. Interestingly, the bacterial PADs are composed of only the approximately 40-kD catalytic domain, whereas mammals have larger multidomain enzymes (≈ 75 kD), whose activity is regulated by calcium. The extra N-terminal domains in the mammalian enzymes include two immunoglobulin-like domains that are proposed to mediate protein-protein interactions and/or substrate targeting.¹²⁸ To date, five human PAD homologs have been identified and the *PADI* genes are located at a single cluster on chromosome 1p36.1.^{43,129} For historical reasons, these isozymes are designated PAD1-4 and PAD6. Human PAD4 was initially named PAD5 but was later renamed PAD4 to reflect the fact that it is a true ortholog of this isoform.¹³⁰ PAD4 is the only PAD that resides in the nucleus, a function of its nuclear localization sequence.¹³¹

The PADs share 50% to 55% sequence identity with each other,¹²⁸ with different PADs preferentially expressed in specific tissues. PAD1 is primarily expressed in uterus and skin. PAD2 is more widely expressed in muscle, skin, brain, spleen, rheumatoid synovium, and secretory glands. PAD3 is also expressed in skin, PAD4 is expressed in hematopoietic cells, and PAD6 is found in germ cells and peripheral blood leukocytes.^{43,82,129,130,132-134} Because of their prominent expression in rheumatoid synovial tissue and fluid,^{95,135,136} PAD2 and PAD4 have gained prominence as potential candidates that drive citrullination of self-antigens in RA.

Peptidylarginine Deiminase Structure, Activity, and Regulation

The three-dimensional structure of PAD4 has been solved^{128,137} and is likely representative of the broader family. PAD4 is a dimer formed by head-to-tail contact between the N-terminal domain of one molecule and the C-terminal domain of the second. Each monomer adopts an

elongated fold in which the N-terminal domain forms two immunoglobulin-like subdomains (named subdomain 1 and 2), and the C-terminal domain forms an α/β propeller structure. Five Ca^{2+} -binding sites were identified in the structure, and Ca^{2+} binding induces conformational changes required to generate the active site cleft. Thus PADs rely strongly on the presence of Ca^{2+} for activity and require millimolar amounts of calcium to be activated *in vitro*. Because calcium concentrations in cells do not rise above the low micromolar levels, the mechanisms that control PAD activation *in vivo* remain unclear. One possible explanation for the requirement of “extracellular” concentrations of calcium to achieve PAD activation is that protein citrullination occurs under extreme conditions where intracellular concentrations of Ca^{2+} approach extracellular concentrations (e.g., during necrosis or apoptosis).¹⁰⁸ Whether other mechanisms regulate PAD enzyme activation, potentially by modifying the calcium requirement (e.g., allosteric effects of post-translational modifications or partner-binding), is not known. It is also important to note that although PAD activation provides one level of regulation, the activity of the PADs can also be negatively regulated through autocitrullination. This is not dissimilar to other enzymes, where automodification (e.g., autophosphorylation) modifies enzymatic function. Autocitrullination has been described for PADs 1, 2, 3, and 4.^{90,138} In the case of PAD4, direct citrullination of arginines surrounding the active site cleft appears to have a major impact on activity.⁹⁰

Structural and Functional Implications of Protein Citrullination

Arginine residues often play a central role in the maintenance of tertiary structure in proteins because the positively charged guanidino group is a versatile interacting partner, forming multiple intramolecular hydrogen bonds to backbone carbonyl oxygens, and also intermolecularly between different proteins.¹³⁹ Thus during the process of citrullination, the conversion of arginine into citrulline reduces the net charge of the protein by the loss of a positive charge per citrulline residue. In addition, by changing the guanidino group in arginine to an ureido group in citrulline, arginine deamination may modify intramolecular and intermolecular interactions, producing changes in protein structure.¹⁴⁰

These structural changes likely also have important functional implications. Indeed, deimination has been implicated in several physiologic processes. In the skin (which expresses PADs 1, 2, and 3^{48,133,141}), deimination of filaggrin (a component of the cornified cell envelope) is critical for its degradation into free amino acids, which act as a natural moisturizing factor in the stratum corneum.^{48,141} Interestingly, PAD2-deficient mice have normal development and show no abnormalities in the skin,¹⁴² suggesting functional redundancy in mouse development. Whether PAD2 functions in the skin during injury or environmental perturbations is currently unknown. In the immune system, PAD2 (and/or potentially other PADs) citrullinates chemokines, a process that decreases chemokine activity.¹⁴³⁻¹⁴⁶ Thus PAD2 may play important roles in controlling effector functions related to environmental triggers.

Human PAD4 (first called PAD5) was first found in human myeloid leukemia HL-60 cells induced to

differentiate into granulocytes by retinoic acid¹³⁰ and later described in peripheral blood granulocytes.¹³² The expression of PAD4 during granulocyte differentiation initially suggested that this enzyme may have a role during granulopoiesis. Histones H2A, H3, and H4, as well as nucleophosmin/B23, were the first PAD4 substrates to be identified.¹⁴⁷ PAD4 appears to function as a transcriptional co-regulator, mediated by its ability to catalyze the deimination of specific residues present in the N-terminal tails of histones.¹⁴⁸⁻¹⁵⁰ Interestingly, mice deficient in PAD4 also have normal development,¹⁵¹ suggesting that this enzyme has no essential roles in steady-state cellular functions and/or development. Recent studies have demonstrated that PAD4-mediated citrullination of histones is required for NET (neutrophil extracellular traps) formation and bacterial clearance,^{150,151} suggesting a role for this enzyme in immune and inflammatory effector functions.

PAD6, the most recently defined member of the PAD family, was initially cloned from mouse oocytes and named egg PAD (ePAD).¹⁵² PAD6 is essential for the formation of cytoplasmic lattices, and female mice deficient in PAD6 are infertile but otherwise normal.¹³⁴

Peptidylarginine Deiminases in Rheumatoid Arthritis

Multiple PADs are likely responsible for autoantigen citrullination in RA, particularly PADs 2 and 4^{95,135,136} (see Figure 56-2). Although PAD4 has some unique characteristics that have focused significant attention on this protein, it is important to be aware that there is no evidence to suggest that pathologic citrullination in RA is exclusively or preferentially mediated by this isoform.

It is of interest that several polymorphisms in PAD4 have been genetically associated with RA development, particularly in Asian populations¹⁵³⁻¹⁵⁶ (see Figure 56-2). In this regard, two common haplotypes of the *PADI4* gene were initially identified¹⁵³ and designated “susceptible” or “non-susceptible” on the basis of their relative frequency in patients with RA versus controls. In the initial population, the odds ratio for the susceptible haplotype was almost 2; this effect was not observed in most Caucasian populations. Changes in mRNA stability of the susceptible *PADI4* reported in the initial paper were not associated with changes in enzyme level. Furthermore, although the susceptible haplotype generates a PAD4 molecule containing three amino acid substitutions in the N-terminal region (i.e., Gly55-Ser, Val82-Ala, Gly112-Ala), current evidence suggests that these changes have no effect on the function of the protein.^{90,157} Indeed, they appear to affect conformation only within the N-terminal domain, but not the active site located in the C-terminal domain.¹⁵⁷ The fact that PAD4 acts as a head-to-tail dimer may nevertheless allow conformational differences in the N-terminus of one molecule to influence the C-terminal domain of another and influence catalysis or even inhibition by autocitrullination. It has been proposed that PAD4 genotype may exert its effects on RA disease susceptibility as a consequence of its immunogenicity, rather than its enzyme activity.⁹⁰

Consistent with this hypothesis is the observation that, in addition to its ability to citrullinate RA autoantigens, PAD4 itself is an RA autoantigen, even in the

noncitrullinated form¹⁵⁸⁻¹⁶⁰ (see Table 56-1 and Figure 56-2). The sensitivity of PAD4 antibodies for RA is in the 30% to 40% range, with specificity of greater than 95%. PAD4 autoantibodies are associated with more severe, erosive RA that persists despite treatment with tumor necrosis factor (TNF) inhibitors^{160,161} and, like anti-CCP, are frequently present early before onset of any symptoms.⁷⁴ Interestingly, the susceptible PAD4 haplotype was strikingly associated with PAD4 autoantibodies, even in Caucasian populations in whom the RA disease association was not evident.¹⁵⁹

Genetic Associations with Anti-CCP/ACPAs

Although the association of specific HLA-DR alleles and RA has been known for decades, the relationship between genetics and the development of RA autoantibodies is just beginning to be elucidated.¹⁶² A subset of HLA-DR alleles termed the “shared epitope” (SE) alleles includes HLA-DR*0101, *0102, *0401, *0404, *0405, *0408, *0410, *1001, and *1402 and is united by a conserved sequence of amino acids (QRRRAA, QKRRAA, or RRRRAA) on the α -helix of the DR- β chain peptide binding groove.¹⁶³ SE alleles are strongly associated with the development of anti-CCP/ACPA but are not independently associated with RF⁵⁹ (Figure 56-3). Furthermore, there appears to be a gene dosage effect on the relative risk of anti-CCP development with an odds ratio of 3.3 to 4.7 for patients with one SE allele and an odds ratio of 11.8 to 13.3 for patients with two SE alleles.^{59,164,165} Analysis of individual SE alleles has revealed that anti-CCP/ACPAs are predominantly associated with HLA-DR4 rather than HLA-DR1 SE alleles.⁹⁸ Interestingly, smoking has been shown to skew the genetic association of SE alleles with anti-CCP development, with HLA-DR1 and HLA-DR10 SE alleles being more important in this patient group (see “Autoantibodies in Rheumatoid Arthritis: Insights into Disease Mechanism” later).¹⁶⁶

In addition to SE alleles, a single nucleotide polymorphism in the *PTPN22* gene (1858C/T) is also associated with anti-CCP antibodies with an odds ratio of 3.80¹⁶⁷ (see Figure 56-3). *PTPN22* encodes for lymphoid protein tyrosine phosphatase and has been shown to be associated with several autoimmune disorders including RA.¹⁶⁸ The combination of *PTPN22* 1858C/T genotype and anti-CCP antibodies was 100% specific for RA and confers a relative risk of 130.03. The 1858C/T polymorphism was not associated with RF isotypes and appeared to act independently of SE alleles.¹⁶⁷ Genetic factors such as the SE and *PTPN22* may therefore play a role in the preclinical phase of RA, predisposing individuals to the generation of anti-CCP antibodies and susceptibility to the overt disease phenotype.

OTHER AUTOANTIBODY SPECIFICITIES IN RHEUMATOID ARTHRITIS

Anti-RA33 antibodies were discovered in 1989 as a novel autoantibody specificity recognizing a nuclear protein with an apparent molecular mass of 33 kD¹⁶⁹ (see Table 56-1). These autoantibodies were initially detected in 35% of RA patients but in a small number of patients suffering from

other autoimmune or degenerative rheumatic disorders. The antigen was termed RA33, and it was the first description of a nuclear antigen apparently specific for RA. Later, the antigen was identified as the A2 protein of the heterogeneous nuclear ribonucleoprotein complex (hnRNP-A2).¹⁷⁰ Further characterization of this antibody showed that it was not strictly specific for RA but also found in approximately 20% of patients with SLE and in 40% to 60% of patients with mixed connective tissue disease (MCTD).^{171,172} However, in SLE and MCTD they usually occur together with antibodies to U1-snRNP or Sm. Therefore anti-RA33 without concomitant anti-U1-snRNP autoantibodies were found to have specificity of 96% for RA.¹⁷¹ Additionally, anti-RA33 antibodies in RA, SLE, and MCTD are distinguished by their recognition of different conformation-dependent epitopes in hnRNP-A2.¹⁷³ Interestingly, despite their limited specificity, in the absence of RF and ACPAs, anti-RA33 antibodies in patients with very early arthritis (<3 months' duration) are associated with a relatively mild nonerosive disease course, potentially identifying patients with a good prognosis who will respond well to treatment with disease-modifying antirheumatic drugs.¹⁷⁴

In studies in human samples, stimulation assays using hnRNP-A2 induced T cell proliferation in almost 60% of the RA patients (which were largely HLA-DR-restricted); T cell proliferation in response to hnRNP-A2 was present in only 20% of the controls, with substantially stronger responses in RA patients.¹⁷⁵ Interestingly, immunohistochemical analyses revealed pronounced overexpression of hnRNP-A2 in synovial tissue of RA patients, placing the antigen at sites of pathology in RA. Another autoantigen of potential interest in RA is glucose-6-phosphate isomerase (G6PI). Arthritis in the K/BxN mouse model results from pathogenic immunoglobulins that recognize G6PI,¹⁷⁶⁻¹⁷⁸ a glycolytic enzyme residing in the cytoplasm of all cells. Moreover, antibodies directed against G6PI can, alone, transfer arthritis to healthy recipients.¹⁷⁹ Considering the pathogenic potential of this antibody, researchers were prompted to study it in human RA. However, although initial studies reported a high frequency of such antibodies in RA patient sera,¹⁸⁰ these results have been the subject of debate.¹⁸¹⁻¹⁸³ Overall, anti-G6PI antibodies in RA patients range from 12% to 29% in different cohorts, with a higher prevalence in patients with active disease. Psoriatic arthritis, undifferentiated arthritis, and spondyloarthropathy patients also displayed anti-G6PI antibodies at similar frequencies (12% to 25%), and similar titers are detected in a proportion (5% to 10%) of control subjects or patients with Crohn's disease or sarcoidosis.¹⁸³ The potential relevance of these antibodies in RA is still uncertain.

More recently, homocitrulline-containing proteins (i.e., carbamylated proteins) have been recognized as an important target of autoantibodies in RA,¹⁸⁴ with IgG and IgA antibodies recognizing carbamylated antigens identified in more than 40% of patients with RA.¹⁸⁵ Most carbamylation *in vivo* is believed to take place during inflammation when myeloperoxidase is released from neutrophils.^{186,187} Although homocitrulline resembles citrulline (homocitrulline is one methylene group longer, but similar in structure), the finding that anticarbamylated protein antibodies are predictive for a more severe disease course in ACPA-negative patients has suggested that these antibodies are

ASYMPTOMATIC PHASE

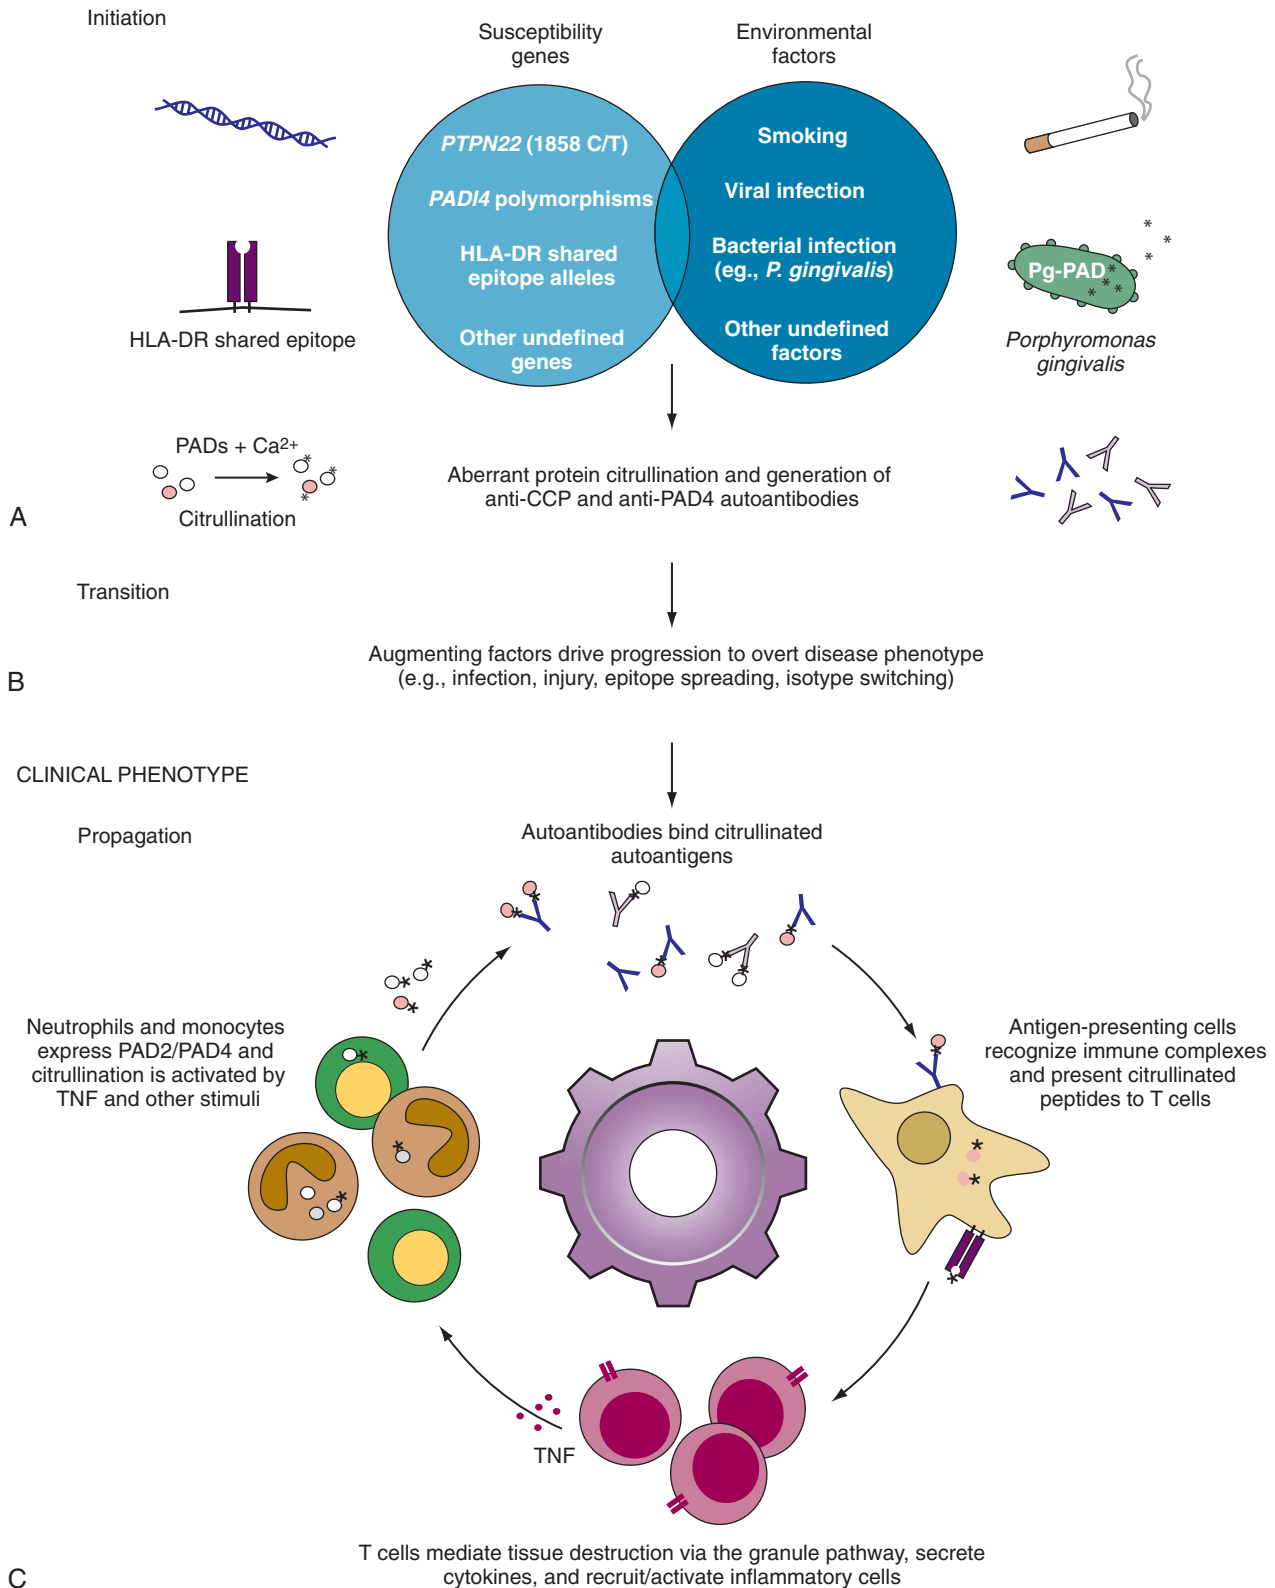

Figure 56-3 A feed-forward model of rheumatoid arthritis pathogenesis: a pivotal role for protein citrullination. **A**, During disease initiation, disease susceptibility genes interface with environmental factors to trigger aberrant protein citrullination and the development of autoantibodies. Citrullinated antigens are indicated (*). The asymptomatic initiation phase may persist for several months to decades before the onset of clinical symptoms, with circulating autoantibodies to citrullinated proteins being detectable during this time. **B**, Undefined transition events prompt the shift from the asymptomatic phase to the overt clinical phenotype. **C**, Once initiated, the immune response drives a feed-forward loop of target tissue destruction and disease propagation resulting in the clinical phenotype. Although aberrant protein citrullination may initially occur outside the joint, during disease propagation, citrullinated autoantigens are generated in the synovium by inflammatory cell peptidylarginine deaminases (PADs), leading to amplification of the immune response within the target tissue. anti-CCP, anticyclic citrullinated peptide; TNF, tumor necrosis factor.

not cross-reactive.¹⁸⁵ Although the study of these novel autoantibodies is still in an early phase, it is likely that this is another post-translational modification that plays a central role in generating the autoantigens targeted in RA.

AUTOANTIBODIES IN RHEUMATOID ARTHRITIS: INSIGHTS INTO DISEASE MECHANISM

Although the pathogenesis of RA remains incompletely understood, current models employ a similar construct to other autoimmune rheumatic diseases; that is, in the setting of a complex genetic predisposition, environmental and stochastic events function to initiate an autoimmune process recognizing specific self-antigens, where the immune response itself participates in immune amplification and tissue injury (see Figure 56-3). The striking association of RA (and particularly ACPA) with particular major histocompatibility complex (MHC) class II alleles underscores at least one component of this framework. Whether RA autoantibodies are directly pathogenic or whether they are markers of inflammation and/or damage remains uncertain, particularly for RFs. However, ACPAs have several features that suggest direct involvement in RA pathogenesis (see Figure 56-2): (1) The targets of these antibodies (i.e., citrullinated proteins) are abnormally expressed and highly enriched in synovial tissue and fluid of RA patients^{85,95,136}; (2) the antibody response directed against these citrullinated antigens precedes RA onset^{17,71,77,188} and is highly specific for RA and predictive of disease progression^{62-66,189}; (3) ACPA positivity is closely linked with the best known predisposing genetic risk factors for the development of RA: the HLA-DR shared epitope (SE) alleles,^{164,167,190,191} in particular, HLA-DRB1*04,^{98,192,193} linking genetic predisposition and autoantibody production; (4) plasma cells producing antibodies against citrullinated proteins are present in RA synovial tissue⁴⁶; (5) about half of the anti-CCP-positive RA patients have circulating immune complexes containing citrullinated fibrinogen, and immunohistochemical staining has shown co-localization of fibrinogen, immunoglobulin, and complement component C3 in RA pannus tissue¹⁹⁴; and (6) immune complexes containing citrullinated fibrinogen can also activate monocyte-derived macrophages to produce TNF via engagement of Fcγ receptors and TLR4.^{195,196} Similar observations implying overlapping pathogenic properties are likely also operative in the case of RFs in RA. There is also recent evidence that Fc-linked glycosylation patterns of immunoglobulins differ in RA and may influence pathogenicity of these antibodies.

Potential Environmental Factors in ACPA Production and Rheumatoid Arthritis Pathogenesis

Although abundant citrullination is found in RA synovial tissue once disease is established, no studies have addressed whether abnormal synovial citrullination precedes the onset of clinical RA (a requisite to explain the presence of antibodies against citrullinated proteins long before clinical disease). Such evidence will be challenging to obtain. At

this stage, it is therefore important to be aware that the joint is not the only possible site of abnormal citrullination that might initiate the RA-specific immune responses to citrullinated autoantigens, and it is possible that the joint only becomes targeted secondarily after the ACPA immune response has been initiated at another site, as a consequence of an inflammatory event triggered by a common environmental exposure such as periodontal infection/inflammation and/or smoking (see Figure 56-3). Although there is no evidence that viral proteins are citrullinated *in vivo*, a subset of ACPA-positive RA sera has been demonstrated to cross-react with *in vitro* citrullinated peptides from Epstein-Barr virus EBNA-1 and human papillomavirus (HPV)-47 E2₃₄₅₋₃₆₂ proteins.^{197,198} Defining the kinetics of appearance of these antibodies during disease development and demonstrating directly that these modified proteins are generated during natural infection will be important to determine if this cross-reactivity is relevant to RA pathogenesis.

There are tantalizing similarities and epidemiologic associations between periodontitis and RA including presence of bone erosions, association with similar MHC class II alleles and smoking, and enrichment of severe periodontal disease in patients with RA.¹⁹⁹⁻²⁰³ These connections have focused attention on the study of oral pathogens that express enzymes with PAD activity, specifically *Porphyromonas gingivalis*.²⁰⁴ This is a gram-negative bacterium commonly present as a biofilm in the gingival crevice and intracellularly in oral epithelial cells. This organism uses numerous virulence factors to evade host defenses as it establishes itself as one of the predominant pathogens in periodontal pockets. *P. gingivalis* expresses its own citrullinating enzyme named PgPAD, which produces ammonia that likely has negative effects on neutrophil function.²⁰⁵ PgPAD is not an ortholog of mammalian PADs, having no sequence homology with mammalian PADs and showing significant differences in citrullination activity: (1) PgPAD can citrullinate free L-arginine in addition to protein-bound arginine, (2) the enzyme does not require calcium or any other metal ion for activity, and (3) it has stronger preference for citrullination of C-terminal arginines. *P. gingivalis* also produces arginine gingipains, endopeptidases that cleave substrates after arginine residues, a process that generates C-terminal arginine in substrates, which are then citrullinated by PgPAD.²⁰⁵ Interestingly, both arginine gingipain and PgPAD are secreted and have been shown respectively to cleave and citrullinate human fibrinogen and α-enolase in solution.²⁰⁶ *P. gingivalis* per se contains a large number of endogenous citrullinated proteins.²⁰⁶ Thus either as a source of bacterial citrullinated proteins and/or bacterial enzymes that generate host protein citrullination, *P. gingivalis* has been proposed as a potential factor responsible for initiating an immune response against citrullinated proteins, in individuals genetically predisposed to developing RA. Interestingly, when *P. gingivalis* enolase is citrullinated *in vitro*, it is recognized by human antibodies against CEP-1, the immunodominant peptide from citrullinated human α-enolase.¹¹⁶ The noncitrullinated *P. gingivalis* enolase was not similarly recognized. Although it remains to be demonstrated whether bacterial enolase is citrullinated by the bacterial enzyme or even by host PADs (a process that may occur during bacterial lysis by phagocytic cells expressing PADs), these initial findings raise the intriguing possibility that ACPA specific-

ity might be initially driven by bacterial products, which are subsequently driven by citrullinated endogenous proteins in the microenvironment of the inflamed joint (see Figure 56-3).

Another environmental factor with potential relevance in initiating production of ACPAs is cigarette smoking (see Figure 56-3). Interestingly, recent evidence has demonstrated (at least in some populations) a strong interaction between smoking and SE alleles in the development of ACPA-positive RA.^{166,207-209} However, although primarily HLA-DRB1*04 alleles have been associated with ACPA production,^{98,192,193} in smokers, HLA-DRB1*0101, *0102, and *1001 alleles showed the closest association with positive anti-CCP.¹⁶⁶ The observations that cigarette smoking induces increase expression of PAD2 and protein citrullination in lungs⁵¹ and that anti-CCP antibodies of the IgA class are found in about one-third of patients with recent-onset RA²¹⁰ have suggested that the lung or other mucosal surfaces may play a role in generating or sustaining autoantibodies to citrullinated proteins. These gene-environment interactions, playing out in microenvironments outside the joint, add important dimensions to the framework within which RA pathogenesis must be investigated and understood. Although it is possible that none of the detailed mechanisms currently defined represent the unifying mechanism of pathogenesis in RA, the broader view of potential immunizing environments and the search for a frequent worldwide environmental exposure are of great importance.

Role of Autoantibodies in Rheumatoid Arthritis: Insights from Animal Models

Although animal models are not ideal settings to define the role of human ACPA in RA, several *in vivo* models have provided evidence to support a pathogenic role for these antibodies in inflammatory arthritis in animals.

1. The conversion of peptidylarginine to peptidylcitrulline significantly increases affinity of the interaction of peptides with the RA-associated HLA-DRB1*0401 MHC class II molecule (shared epitope) and leads to the activation of CD4⁺ T cells in human HLA-DRB1*0401 transgenic mice.²¹¹
2. Citrullinated human fibrinogen can induce arthritis in mice transgenic for human HLA-DRB1*0401.²¹² Transgenic and wild-type mice were immunized with unmodified or citrullinated human fibrinogen. Approximately one-third of transgenic mice immunized with citrullinated fibrinogen but none of those immunized with unmodified fibrinogen developed inflammatory arthritis, although with some histologic features that were not entirely typical of human RA. Interestingly, wild-type mice immunized with either form of fibrinogen did not develop arthritis. These data indicate the importance of both the susceptible human MHC II genotype, in this case DRB1*0401, and citrullination of the antigen, in this case the human antigen, in mediating pathology. Although this initial study strongly supports the potential pathogenic role of protein citrullination in RA, there appears to be specificity for the citrullinated molecules because not all citrullinated antigens are similarly able

to induce/amplify disease. For example, noncitrullinated and citrullinated collagen type II are both potent inducers of arthritis in rats, although the citrullinated form induced arthritis with slightly higher incidence and earlier onset.²¹³ In the same experiments, citrullinated rat albumin was also used to immunize rats. However, despite the fact that the rats developed a strong immune response against citrullinated albumin, the rats had no signs of disease, demonstrating that an immune response toward any citrullinated protein is clearly not enough to induce clinical arthritis.

3. Antibodies against citrullinated proteins enhance tissue injury in experimental autoimmune arthritis. In this model, murine monoclonal antibodies specific to citrullinated fibrinogen were shown to enhance arthritis when co-administered with a submaximal dose of anticollagen II antibodies. These antibodies were shown bound to targets within the inflamed synovium of treated mice.²¹⁴

KEY POINTS

Inflammation comprises a complex and highly variable set of processes that represent a response to tissue damage from infection or injury.

The acute phase response, a major accompaniment of inflammation, is induced by inflammation-associated cytokines and includes reorchestration of acute phase protein synthesis by the liver.

The erythrocyte sedimentation rate (ESR), the most commonly employed clinical measure of inflammation, depends on numerous physical and chemical characteristics of blood, many of which are not related to inflammation.

The quintessential acute phase protein, C-reactive protein (CRP) not only offers biomarker utility in the clinic but also, plays a role in host defense by recognition of biologic substrates, activation of the complement pathway, and binding to leukocytes.

Cytokines, chemokines, adhesion molecules, and other products of activated inflammatory cells are secreted during and play roles in the inflammatory response, but several problems limit the clinical usefulness of their quantitation for routine clinical purposes.

CRP and ESR may reflect disease activity and correlate with disease prognosis in rheumatoid arthritis but generally are not helpful for differential diagnosis.

Although CRP and ESR correlate with clinical activity in many inflammatory rheumatic diseases, the absent or modest CRP response seen in some patients with active systemic lupus erythematosus remains unexplained.

CRP or ESR is elevated in more than 80% of patients with polymyalgia rheumatica and in about 95% of patients with giant cell arteritis; both are useful for disease follow-up, but their imperfect correlation with disease activity indicates that these measures cannot supplant sound clinical judgment.

Minor "elevations" of CRP, within the normal population reference range, are associated with increased risk of myocardial infarction but are nonspecific (especially in patients with rheumatic disease). Minor CRP elevation is associated with well-recognized risk factors for cardiovascular disease, which may explain its predictive value.

The inflammatory response is the body's natural defense against unchecked tissue damage from infection or injury. It occurs during the acute phase of an inciting event and, if the stimulus is not eliminated, in a chronic, healing stage. When excessive or uncontrolled, these responses have the potential to cause significant harm to the host through

Acute Phase Reactants and the Concept of Inflammation

AMIT SAXENA • BRUCE N. CRONSTEIN

processes such as autoimmune diseases, allergic reactions, and septic shock.

The concept of inflammation itself has evolved over thousands of years; Celsus first described the cardinal signs of redness, swelling, heat, and pain in the 1st century AD. The fifth sign, loss of function, is often attributed to Galen's work during the 2nd century.¹ Since that time, countless advances have been made in the understanding of inflammation, from histologic findings of inflammatory cells within tissues, to the discovery of hematologic and soluble mediators such as cytokines and complement. Also, the molecular signaling pathways that drive both its protective effects and the inappropriate injurious responses have been recently elucidated.

With increasing insight into mechanisms of the inflammatory response has come an appreciation of its significant complexity. Molecular and microscopic processes are different during acute and chronic stages, and diverse responses are induced by various types of exogenous and endogenous stimuli (e.g., bacteria, viruses, parasites, crystals, allergens, ischemia). More recently, the role of the milieu of the inflammatory response, especially at the level of the vascular endothelium, has taken on considerable importance.² Furthermore, inherent redundancies of functions have been noted, as have interactions between the mediators of inflammation that allow for a broad, effective response, but these redundancies make it difficult to understand the pathways of inflammation in a linear fashion. These intricacies have resulted in a vague definition and on continued reliance on the final downstream macroscopic cardinal signs to tie together all of the ongoing processes. It is these same intricacies that have made evaluation of inflammation through laboratory tests imprecise.

Basic hematologic abnormalities may give clues to the presence of inflammation, but different patterns are often associated with underlying causes and are not universally found. Leukocytosis can be seen in infections, acute crystal diseases, and some autoimmune disorders such as adult Still's disease. Anemia is often associated with certain diseases that cause chronic inflammation, such as rheumatoid arthritis (RA). Reactive thrombocytosis occurs secondary to the release of cytokines after an inciting infectious or inflammatory event, and the role of platelets and platelet-derived mediators in stimulating inflammation has been described at the molecular level.³

Laboratory tests most commonly used by physicians to objectively obtain information about the extent of inflammation are those that measure the acute phase reaction. In response to injury, local inflammatory cells secrete cytokines that influence the liver to increase or decrease production of various proteins. The erythrocyte sedimentation rate

(ESR) has been the classic marker of inflammation, with serum C-reactive protein (CRP) taking on an increasingly prominent role. Other novel inflammatory markers have been recognized but have not been found to be more clinically useful.

CRP elevations, especially minor ones, have been noted in numerous conditions that traditionally have not been considered inflammatory, most significantly involving the cardiovascular system. This has shed light on subclinical inflammation as a possible factor in the pathogenesis of a great number of diseases.

ACUTE PHASE RESPONSE

Within minutes of tissue injury, activation of the innate immune system induces cytokine production that results in a multisystem acute phase response involving the liver, vascular system, bone marrow, and central nervous system.^{4,5} Many elements of the reaction can be regarded as part of the innate response and are defensive or adaptive in nature.⁶ Mouse studies have shown that up to 7% of the regulatable gene pool undergoes significant changes in expression during inflammation, and that induction of liver acute phase genes is mediated by the transcription factor signal transducer and activator of transcription 3 (STAT3).⁷⁻⁹

Although the acute phase response can trigger numerous neuroendocrine, hematopoietic, and metabolic effects, it is the changes in plasma proteins synthesized by hepatocytes that are monitored as signs of underlying inflammation (Tables 57-1 and 57-2). An acute phase protein is one whose plasma concentration changes from baseline by at least 25% during inflammation; responses vary in terms of concentration and kinetics (Figure 57-1).¹⁰ CRP and serum amyloid A (SAA) levels increase more than 1000-fold during acute infection, and peak at 2 to 3 days. Concentrations of other proteins peak at longer periods and can range from a 50% increase in complement and ceruloplasmin, to a several-fold amplification in haptoglobin, fibrinogen, α_1 -proteinase inhibitor, and α_1 -acid glycoprotein. Other proteins are negative acute phase proteins whose concentrations fall during the inflammatory response. These include antithrombin III, protein S, prealbumin, albumin, transferrin, and apolipoprotein A-I.^{4,5}

Hepatic stimulation of acute phase proteins is induced by cytokines released by activated monocytes, macrophages, neutrophils, natural killer (NK) cells, and endothelial cells acting at the front lines of the inflammatory response. The main cytokine influencing the liver is interleukin (IL)-6, once called the “hepatocyte-stimulating factor.” It likely mediates protein expression via the Janus-activated kinase (JAK) and STAT3 pathways, as well as C/EBP family members and Rel proteins (nuclear factor κ B [NF κ B]).^{9,11} During initial stages, IL-1 and tumor necrosis factor (TNF) synergize with IL-6 and trigger further IL-6 production, but their roles are limited.¹² The soluble IL-6 receptor amplifies IL-6 effects both locally and systemically. IL-6 also performs a protective role during disease, inducing the expression of an IL-1 receptor antagonist.¹³

Acute phase protein levels are not uniform in their expression; this is likely related to the underlying pathophysiologic state and is regulated by different combinations and interactions of cytokines.⁵ The roles of the acute phase

proteins themselves will be discussed throughout the chapter but have been found to include direct involvement in host defense by activation of the complement, proteinase inhibition, and antioxidant activity.¹⁴ However, some of the described in vitro effects of proteins may not be relevant in vivo.

Erythrocyte Sedimentation Rate

Although ESR is an indirect screen for elevated concentrations of acute phase proteins, it has been the most widely used marker of inflammation for almost a century.

Measurement of ESR is performed when blood is placed in a vertical tube and the rate of fall of erythrocytes is measured. The ancient Greeks recognized increased red blood cell (RBC) sedimentation as a way to detect “bad bodily humors,” but our modern understanding and use of RBC sedimentation as a test date back to the German scholar Fahraeus in 1918.¹⁵ He determined that certain plasma proteins, especially fibrinogen, are able to lower the electrostatic charge on RBC surfaces so they can aggregate, form rouleaux, and fall faster.

Several factors are involved in acceleration of ESR. Asymmetric plasma proteins such as fibrinogen and, to a lesser extent, α_2 , β , and γ globulins decrease the negative charge of erythrocytes (zeta potential) that prevents rouleaux formation. Red cell factors also play a role in that changes in plasma ratios in anemic states also favor rouleaux. However, microcytosis, polycythemia, and abnormally shaped RBCs (e.g., sickle cells, spherocytes) hinder aggregation and lower the ESR.¹⁶ Conditions that elevate fibrinogen, even if they are not necessarily considered inflammatory, can raise ESR. These include pregnancy, diabetes, end-stage renal disease, and heart disease. Major increases in the concentration of a single molecular species, such as a monoclonal immunoglobulin in multiple myeloma, also cause increased sedimentation.¹⁷ The ESR is elevated in obesity, as is CRP, presumably as a result of IL-6 secretion by adipocytes.¹⁸ Factors such as glucocorticoids, cryoglobulins, hypofibrinogenemia, and hyperviscosity have been shown to lower the value.⁴ The physiochemical dynamics that allows for sedimentation has been a continued source of debate, with disparate models presented to explain

Figure 57-1 Typical plasma acute phase protein changes after a moderate inflammatory stimulus. Several patterns of response are seen: major acute phase protein, increase 100-fold (e.g., C-reactive protein, serum amyloid A); moderate acute phase protein, increase twofold to fourfold (e.g., fibrinogen, haptoglobin); minor acute phase protein, increase 50% to 100% (e.g., complement C3); and negative acute phase protein, decrease (e.g., albumin, transferrin). (Adapted from Gitlin JD, Colten HR: *Molecular biology of the acute-phase plasma proteins*. In Pick E, Landy M, editors: *Lymphokines*, vol 14, San Diego, 1987, Academic Press, pp 123–153.)

Table 57-2 Other Acute Phase Phenomena

Neuroendocrine Changes
Fever, somnolence, and anorexia
Increased secretion of corticotropin-releasing hormone, corticotropin, and cortisol
Increased secretion of arginine vasopressin
Decreased production of insulin-like growth factor I
Increased adrenal secretion of catecholamines
Hematopoietic Changes
Anemia of chronic disease
Leukocytosis
Thrombocytosis
Metabolic Changes
Loss of muscle and negative nitrogen balance
Decreased gluconeogenesis
Osteoporosis
Increased hepatic lipogenesis
Increased lipolysis in adipose tissue
Decreased lipoprotein lipase activity in muscle and adipose tissue
Cachexia
Hepatic Changes
Increased metallothionein, inducible nitric oxide synthase, heme oxygenase, manganese superoxide dismutase, and tissue inhibitor of metalloproteinase-1
Decreased phosphoenolpyruvate carboxykinase activity
Changes in Nonprotein Plasma Constituents
Hypozincemia, hypoferremia, and hypercupremia
Increased plasma retinol and glutathione concentrations

From Gabay C, Kushner I: Acute-phase proteins and other systemic responses to inflammation, *N Engl J Med* 340:448–454, 1999.

how proteins on cell surfaces interact to cause RBC aggregation.¹⁹

Although novel and rapid tests for ESR have proved promising, the International Committee for Standardization in Hematology continues to recommend the Westergren technique of testing anticoagulated blood.^{20,21} The usual accepted upper limits of normal are 15 mm/hr for males and 20 mm/hr for females; however, the ESR increases with age and varies by race, calling the reliability of the test into question. A simple formula for calculating the upper limit of normal ESR at any age has been used regularly: In men, age in years divided by 2; in women, 10 plus age in years divided by 2. Despite the ability to control for age, other limitations of the test have been noted and are listed in Table 57-3. The relative virtues of CRP determination have diminished some of the importance of ESR, but it remains an easy, inexpensive test with a wealth of background literature. Therefore the sedimentation rate will continue to play a prominent role in clinical practice.

C-Reactive Protein

C-reactive protein is an acute phase protein whose serum concentration reflects ongoing inflammation better than other tests in most, but not all, diseases.²² CRP was identified in 1930, when sera obtained from patients with *Streptococcus pneumoniae* infection were found to contain a protein that could bind to the “C” polysaccharide of the bacterial cell wall. This protein circulates as a 115-kD pentamer of noncovalently linked 23-kD subunits, which has

Table 57-3 Comparison of Erythrocyte Sedimentation Rate and C-Reactive Protein

	Erythrocyte Sedimentation Rate	C-Reactive Protein
Advantages	Much clinical information in the literature May reflect overall health status	Rapid response to inflammatory stimuli Wide range of clinically relevant values are detectable Unaffected by age and gender Reflects value of a single acute phase protein Can be measured on stored sera Quantitation is precise and reproducible
Disadvantages	Affected by age and gender Affected by red blood cell morphology Affected by anemia and polycythemia Reflects levels of many plasma proteins, not all of which are acute phase proteins Responds slowly to inflammatory stimuli Requires fresh sample May be affected by drugs	None

been highly conserved over hundreds of millions of years of evolution. In contrast to immunoglobulins and complement components, CRP deficiency in humans has not been described. Genome-wide associated studies performed recently have shown that at least seven distinct loci are involved in the basal expression of CRP,²³⁻²⁵ which is upregulated upon stimulation by the transcription factors C/EBP and Rel.²⁶ It is present in trace concentrations in the plasma of all humans (roughly 1 mg/L, with higher concentrations in women and the elderly). Plasma C-reactive protein is synthesized by hepatocytes, although other sites of local production and possibly minimal secretion have been suggested.

The precise function of CRP is unknown and may be varied, but it exhibits important recognition and activation capabilities, and it binds to numerous ligands.²⁷ CRP recognizes phosphocholine, phospholipids, fibronectin, chromatin, and histones, all of which are exposed at sites of tissue damage and by apoptotic cells; CRP may target them for clearance.²⁸ C-reactive protein bridges the gap between innate and adaptive immunity by activating the classical complement pathway and interacting with cells of the immune system through binding of Fcγ receptors.^{29,30} CRP induces inflammatory cytokines, tissue factors, and shedding of the IL-6 receptor, all of which result in a complement-dependent increase in tissue damage.²⁸ Other CRP functions are anti-inflammatory, including promoting the noninflammatory clearance of apoptotic cells and preventing neutrophil adhesion to the endothelium.^{31,32} Thus CRP may play many pathophysiologic roles during the course of the inflammatory process.^{14,33}

After an acute inflammatory stimulus, CRP concentration increases rapidly and peaks at 2 to 3 days at levels that

reflect the extent of tissue injury. If the stimulus has been removed, serum CRP levels drop rapidly, with a half-life of roughly 19 hours.³⁴ Persistent elevations in CRP are seen in chronic inflammatory states such as active RA, pulmonary tuberculosis, or extensive malignant disease.

Immunoassays and laser nephelometry are used at modest cost to quantify serum CRP levels. Most healthy adults have levels less than 0.3 mg/dL. The significance of minor elevations in CRP is being debated and will be discussed subsequently. However, usual methods of CRP determination are less precise at concentrations in the range of 0.3 to 1 mg/dL, so high-sensitivity (hs)CRP methods are used to accurately measure these levels. Generally, concentrations greater than 1 mg/dL reflect clinically significant inflammatory disease.^{35,36} Concentrations of 1 to 10 mg/dL can be considered to represent moderate increases, and concentrations greater than 10 mg/dL show marked increases. Most patients with extremely high levels (e.g., >15 mg/dL) have bacterial infection; one study found that in patients with CRP concentrations greater than 50 mg/dL, infection was present in 88% of subjects.³⁷ Clinical conditions associated with varying degrees of elevation of CRP are listed in [Table 57-4](#), and the range of CRP concentrations in many rheumatologic diseases is shown in [Figure 57-2](#).

Several limitations associated with the use of C-reactive protein measurement must be acknowledged. No uniformity in reporting concentrations has been noted between laboratories, and values can be conveyed in mg/L, μg/mL, or mg/dL. Similar to ESR, population studies show a skewed, rather than Gaussian, distribution, leaving parametric statistical tests inappropriate for interpretation of CRP data. Population differences in CRP levels in the United States have been reported between sexes and among racial groups.

Table 57-4 Conditions Associated with Elevated C-Reactive Protein Levels

Normal or Minor Elevation (<1 mg/dL)	Moderate Elevation (1-10 mg/dL)	Marked Elevation (>10 mg/dL)
Vigorous exercise Common cold Pregnancy Gingivitis Seizures Depression Insulin resistance and diabetes Several genetic polymorphisms Obesity	Myocardial infarction Malignancies Pancreatitis Mucosal infection (bronchitis, cystitis) Most connective tissue diseases Rheumatoid arthritis	Acute bacterial infection (80%-85%) Major trauma Systemic vasculitis

Figure 57-2 Range of C-reactive protein (CRP) levels in rheumatic disease. Authors' estimates of expected levels of CRP (mg/dL) in certain rheumatic diseases.

This is presumably also prevalent as an issue in practice in other populations globally. Elevation of C-reactive protein in the elderly may represent age-related disorders whose pathogenesis may involve low-grade inflammation, complicating the issue of what levels are considered normal.³⁸

Serum Amyloid A

Serum amyloid A (SAA) consists of a circulating family of proteins produced by hepatocytes, adipocytes, macrophages, and fibroblast-like synoviocytes. Although some types are expressed constitutively, the hepatic production of SAA is responsible for an acute phase increase in plasma concentration—up to 1000-fold within 2 days of the inflammatory stimulus.³⁹ SAA is the fibrillar component of amyloid deposits in secondary amyloidosis and is tightly associated with high-density lipoprotein (HDL).⁴⁰

The function of SAA has not been fully defined, although it is generally considered proinflammatory; it likely acts in part through Toll-like receptor (TLR)2 activation of the NFκB pathway and binding to the G protein-coupled formyl peptide receptor like-1 (FPR1).³⁹ These actions induce a variety of cytokines, act as a chemotactic for leukocytes, and stimulate angiogenesis, tissue factor, and matrix metalloproteinase expression.⁴¹⁻⁴⁴ SAA may have a direct role in immunity, acting as an opsonin for gram-negative bacteria and showing antiviral properties *in vitro*.^{45,46} It also has a well-identified role in cholesterol export from cells during inflammatory conditions.^{47,48}

Numerous clinical associations with SAA have been described. Studies have shown correlation with disease activity in a number of inflammatory disorders, possibly more so than with ESR and CRP.⁴⁹ Serum concentrations of SAA secreted by adipocytes correlate with body mass index and may provide a link between obesity and its comorbidities.⁵⁰ The normal level of SAA in healthy adults is less than 10 mg/L, with a median value of 3 mg/L in a European population.⁵¹ The test could be useful in those at risk for secondary amyloidosis, whose probability of survival

was higher than 95% after 6 years for individuals whose median SAA was less than 10 mg/L, but 40% if median SAA remained above 10 mg/L.⁵² However, reliable testing for acute phase SAA is not yet widely available, and data about levels expected in disease are limited.

Other Acute Phase Proteins

Measurement of other acute phase proteins has been of limited value clinically, because their responses to tissue injury are often slower, and the magnitude of concentration change is smaller than with CRP and SAA. Serum ferritin is moderately increased, triggered by cytokines such as IL-1, IL-6, IL-18, and TNF. Levels are frequently high in adult-onset Still's disease and systemic lupus erythematosus (SLE), and they correlate with disease activity.^{53,54} Hepcidin, a liver-derived antimicrobial peptide and regulator of iron homeostasis, is induced by inflammation, and by IL-6 in particular.⁵⁵ Its levels rise in parallel with ferritin, and it is important in the development of anemia of chronic disease, acting as a negative regulator of iron absorption and macrophage iron release teleologically, to deprive microbes of iron.⁵⁶ Transferrin, which binds and transports iron, is a negative acute phase protein.

The prohormone of calcitonin, procalcitonin, is produced by many cell types during severe infection and has been used as a marker to distinguish bacterial infection from other types of inflammatory processes, with some caveats.⁵⁷ Apolipoprotein a-I, the principal protein constituent of HDL, is another negative acute phase protein. In chronic inflammatory diseases such as RA and SLE, decreased levels may contribute to increased risk of thrombotic events.^{58,59} Serum albumin and prealbumin (transthyretin) are also negative acute phase proteins, although their measurement has not been shown to be more helpful in diagnosis or prognosis than standard tests.⁶⁰ Serum complement fractions become depressed when the system is activated in certain autoimmune disorders but otherwise rise during the acute phase response.

Table 57-5 Products of Inflammatory, Endothelial, and Resident Target Tissue Cells/Matrix

Cytokines and Related Molecules	Products of Inflammatory and Endothelial Cells
Cytokines: IL-1 IL-6	Calprotectin von Willebrand factor Soluble adhesion molecules (e.g., sVCAM and sE-selectin)
IL-12 Interferon- α	Hyaluronic acid Collagen and aggrecan degradation products
Tumor necrosis factor Granulocyte-macrophage colony-stimulating factor IL-1 receptor antagonist	Osteocalcin

IL, interleukin.

Cytokines

Although not acute phase proteins in the classic sense, cytokines display the most striking acute phase behavior of any circulating proteins. IL-6 responds dramatically to tissue injury, with concentration changes that are faster and greater than those of CRP or SAA. Acute inflammation and chronic inflammation have been associated with increases in IL-6, and serum levels of this cytokine have been correlated with the severity and course of disease in RA, juvenile arthritis, ankylosing spondylitis, and polymyalgia rheumatica (PMR).^{61,62} It is also more sensitive than ESR for detecting disease activity in giant cell arteritis (GCA).⁶³ IL-6 levels may be useful in monitoring inflammation if hepatocytes are damaged to the point of not being able to synthesize acute phase proteins.⁴ The importance of cytokines such as TNF and IL-1 has been inferred by the successful reduction of inflammation by their therapeutic inhibitors. Certain diseases, such as the TNF receptor-associated periodic syndrome (TRAPS) and the auto-inflammatory syndromes that involve mutations of the inflammasome controlling IL-1, point to the importance of these cytokines.

Increased levels of several other cytokines and circulating cytokine receptors have been associated with inflammation or disease activity as well (Table 57-5).^{63,64} Different patterns of cytokine responses have been reported in different diseases, suggesting that cytokine determinations are potentially useful clinically.^{65,66} However, their quantitation presents several problems related to their short plasma half-lives, the presence of blocking factors and natural inhibitors, and other technical considerations.⁶⁷ At present, high costs, limited availability, and absence of standardization discourage measurement of plasma cytokines and their receptors in clinical practice.

ACUTE PHASE REACTANTS IN THE MANAGEMENT OF RHEUMATIC DISEASES

Measurement of ESR and CRP has no role in the diagnosis of any particular disease, including RA, osteoarthritis, SLE, PMR, GCA, or other inflammatory arthropathies. However, these measurements can be clinically helpful in three ways:

- (1) in evaluating the extent or severity of inflammation, (2) in monitoring changes in disease activity over time, and (3) in assessing prognosis.

Rheumatoid Arthritis

ESR and CRP cannot be used in the diagnosis of RA because 45% of patients may have normal serum levels at presentation,⁶⁸ although these values represent part of the diagnostic syndrome or classification criteria sets. These tests are more appropriately applied in RA for monitoring disease activity and response to therapy. Although ESR traditionally has been more widely used for these purposes, many studies have suggested that CRP levels correlate better with disease activity.⁶⁹ Some recent reports state that CRP levels may overestimate disease response compared with ESR; others claim that differences between the two are minimal.⁶⁹⁻⁷¹ The existence of patients with depressed CRP concentrations caused by carrying low-CRP-associated genetic variants must be taken into account when this test is used universally.⁷² Matrix metalloproteinase (MMP)-3, pro-MMP-3, and soluble E-selectin have also been proposed as markers for RA disease activity; their measurements correlate with CRP levels but do not provide more information than is provided by standard tests.⁷³⁻⁷⁵

CRP levels average 2 to 3 mg/dL in adult RA patients with moderate disease activity.⁷⁶ However, variation is considerable: At least 5% to 10% of patients have values in the normal range, whereas a few patients with severe disease activity have levels greater than 10 mg/dL. ESR values have been found to remain stable over the years.⁷⁷ ESR and CRP have long been used to follow the response to therapy; in general, effective disease-modifying antirheumatic drug therapy decreases CRP by about 40%. Inhibition of joint damage by these agents usually is accompanied by marked improvement in acute phase reactants. Progression of joint damage can occur while the patient is on therapy, however, despite decreases in ESR and CRP.⁷⁸ Even more striking improvement has been seen with biologic agents introduced since the 1990s, providing objective laboratory support for the encouraging clinical responses observed. In early reports of anti-TNF therapy, CRP and SAA levels declined by 75% and 85% in about 1 week.⁷⁹ Treatment with abatacept, the T cell CD80/CD86:CD28 co-stimulation modulator, resulted in significant decreases in CRP at both 90 and 360 days of therapy.⁸⁰ In one study, failure to suppress CRP levels 2 weeks after initiation of infliximab therapy identified most patients who would prove to be clinical nonresponders after 12 weeks.⁸¹ In contrast to traditional disease-modifying antirheumatic drugs, TNF inhibitors have been found to inhibit joint damage even while clinical activity, reflected by CRP levels, remains high.⁸² Tocilizumab, a human IL-6 receptor antibody, improves RA by inhibiting effects of the cytokine. However, owing to its mechanism of action, inflammatory markers such as ESR and CRP drop to negative values, so that tracking them may not reflect the actual effect of the drug; care must be taken when monitoring disease activity during tocilizumab therapy.^{83,84}

ESR and CRP also have value as prognostic indicators in RA. Elevated acute phase reactant levels are associated with early synovitis and erosions as detected by magnetic resonance imaging, with inflammatory cellular infiltrates in

synovium, and with osteoclastic activation and reduced bone mineral density.⁸⁵⁻⁸⁷ CRP predicts radiographic progression, as do ESR and the matrix metalloproteinases MMP-3 and MMP-1.^{73,74,88-90} Finally, and perhaps most important, acute phase reactants correlate with work disability on long-term follow-up and predict progression to major joint replacement.^{91,92} As in the normal population, CRP levels are associated with death from cardiovascular disease.⁹³ In RA patients who developed heart failure, ESR was higher during the 6-month period immediately preceding the onset of heart failure than earlier in their course.⁹⁴

Serum or synovial fluid levels of many other tissue products (see Table 57-5) have been correlated with clinical measures of disease activity, severity, and radiographic damage.

Systemic Lupus Erythematosus

Although serum levels of CRP often parallel disease activity in autoimmune disorders, it has been recognized that SLE is an exception.⁹⁵ Although marked CRP responses are seen in subsets of patients, such as those with serositis or chronic synovitis, many (such as patients with nephritis) show mild or no elevation during periods of activity.⁹⁶⁻⁹⁸ Serum levels of SAA are also relatively low in comparison with those of RA patients.⁹⁹ In contrast, ESR correlates with disease activity and accrued tissue damage in SLE.¹⁰⁰ Fibrinogen levels increased over time in patients, regardless of disease activity.¹⁰¹ Data are insufficient to evaluate the potential use of some of the other newer markers described previously, but many SLE patients with normal CRP levels show elevated IL-6 concentrations.¹⁰² Therefore a deficiency in IL-6 does not explain the muted CRP response in SLE.

Although the concomitant decrease in SAA may point against it, several investigations have raised the possibility that low CRP levels may be related to the pathogenesis of SLE: (1) An association has been noted between SLE and a genetic polymorphism associated with low CRP levels, (2) it has been observed that low CRP levels may contribute to defective clearance of autoantigens during apoptosis, and (3) the therapeutic efficacy of CRP has been reported in mouse models of SLE.^{96,103-106} Recent studies have also raised the possibility that type I interferon (IFN), which has been shown to be expressed significantly in SLE, may inhibit CRP expression.^{107,108}

Substantial CRP elevation in SLE patients is more likely to result from superimposed infection than from activation of lupus. CRP levels greater than 6 mg/dL in these patients should serve as an impetus to exclude the possibility of infection, just as they should in other diseases.¹⁰ Such levels should not be regarded as proof of infection, however; as indicated earlier, marked CRP elevation related to active SLE can be seen in the absence of infection.

Carotid plaque and intima-media wall thickness, correlates of atherosclerotic vascular disease, have been found in association with minor CRP elevation in women with SLE, as they have in patients with RA.^{109,110}

Polymyalgia Rheumatica and Giant Cell Arteritis

The diagnosis of PMR or GCA is supported by an elevated ESR, often greater than 100 mm/hr. However, such

elevation is no longer regarded as a sine qua non of these disorders; continuing reports suggest that 10% to 20% of patients with PMR can have “normal” ESRs, depending on which value is taken as the limit of normal. Such patients tend to have fewer systemic symptoms and less severe, less frequent anemia.¹¹¹ They have the same frequency of positive temporal artery biopsy results, however, as patients with elevated ESR.^{112,113}

Only about 5% of patients with GCA had ESR values less than 40 mm/hr; these patients had fewer visual and systemic symptoms than patients with high ESR values.¹¹⁴ In contrast to these findings, ESR and CRP were found to be significantly lower in patients with ocular involvement, most commonly in the range of 70 mm/hr to 100 mm/hr. Patients with ESR greater than 100 mm/hr had decreased incidence of visual ischemic events.¹¹⁵⁻¹¹⁷

In PMR and GCA, CRP and ESR have been regarded in the past as equally valuable in assessing disease activity. However, recent reports suggest that CRP is more sensitive for both conditions and should be included routinely in the diagnostic workup.^{113,118,119} The report that IL-6 is more sensitive than ESR for indicating disease activity in GCA is of particular interest.¹²⁰ Subsets of patients with PMR who have been noted to have persistently elevated levels of CRP and IL-6 despite corticosteroid treatment have been shown to have a higher risk of relapse.¹²¹ A polymorphism at the IL-6 gene promoter has characterized these PMR patients with persistently elevated levels of the cytokine.¹²² Clinical manifestations of disease, even in the presence of a normal ESR or CRP level, should not be ignored. Extreme elevation of the ESR in the absence of symptoms of PMR or GCA should raise suspicion of other disorders, such as infection, malignancy, or renal disease.

Numerous markers of endothelial perturbation, although not acute phase reactants in the strict sense, are elevated in plasma in various inflammatory disorders of vessels, particularly PMR, GCA, and other vasculitides.¹²³ These molecules include von Willebrand factor, thrombomodulin, some vasoactive prostanoids, and a variety of adhesion molecules, such as vascular cell adhesion molecule-1.

Adult-Onset Still's Disease

Markedly elevated concentrations of ferritin, disproportionately high compared with those of other acute phase reactants, have long been noted in adult-onset Still's disease but are not specific.¹²⁴ Only a low percentage—commonly less than 20%—of ferritin is glycosylated in adult-onset Still's disease—a criterion included in recently proposed classification criteria for this condition.^{125,126} Extremely elevated ferritin levels have been found in macrophage activation syndrome, and 40% of individuals with this condition meet the criteria for adult-onset Still's disease, suggesting to some that the two disorders are not distinct entities.¹²⁷⁻¹²⁹ Concentrations of serum IL-18 were extremely elevated in patients with active adult-onset Still's disease compared with those of patients with other connective tissue diseases or of healthy individuals and were correlated with serum ferritin values and disease severity.¹³⁰ The cytokine profile in the sera of patients suggests a type 1 T helper cell (Th1) response, with significantly higher levels of TNF, IL-6, and IL-8, in addition to IL-18.¹³¹ The role of IL-1 has been

inferred from significant improvement in disease activity by the IL-1 receptor antagonist, anakinra.^{132,133} It has been suggested that interferon- α may be responsible for the hyperferritinemia of adult-onset Still's disease.¹²⁴ CRP levels are usually markedly elevated in this disease.

Ankylosing Spondylitis

Ankylosing spondylitis ordinarily does not lead to a substantial increase in ESR or CRP. Median ESR and CRP levels are 13 mm/hr and 1.6 mg/dL, respectively, in patients with only spinal involvement, and 21 mm/hr and 2.5 mg/dL in patients with peripheral involvement or associated inflammatory bowel disease.¹³⁴ Treatment with infliximab led to an average decrease of 75% in CRP concentration after 12 weeks. Patients with lower CRP levels showed little improvement, however, raising the possibility that patients with higher CRP values show better responses to anti-TNF treatment than do patients with lower CRP levels.¹³⁵⁻¹³⁷ High-sensitivity CRP may better correlate with clinical disease activity compared with standard CRP testing.¹³⁸ It has been reported that levels of IL-8, IL-17, and IL-23 are elevated in the serum of patients with active ankylosing spondylitis, and polymorphisms in the IL-23 receptor gene are associated with the disease.¹³⁹⁻¹⁴¹

Osteoarthritis

Minor CRP elevations of 0.3 to 1.0 mg/dL have been reported in patients with osteoarthritis, particularly those with progressive joint damage.¹⁴² However, no evidence supports this association independent of body mass index (BMI), because obesity is a common accompaniment of osteoarthritis.¹⁴³ Although local inflammation likely plays a role in the pathogenesis of osteoarthritis, systemic inflammation likely does not. However, CRP levels are higher in patients with erosive osteoarthritis of the hand than in those with nonerosive osteoarthritis.¹⁴⁴

Other Rheumatic Diseases

Acute phase markers are elevated in numerous rheumatic diseases as the inflammatory cascade commences. Elevated ESR and CRP can be found in systemic vasculitides, crystal arthropathies, psoriatic and reactive arthritides, and infectious joint diseases.¹⁴⁵⁻¹⁴⁸ Monitoring for elevated SAA levels has been proposed as a tool for diagnosis and medication adjustment in familial Mediterranean fever.¹⁴⁹ CRP is often normal in patients with primary Sjögren's syndrome, and those with elevated responses do not differ clinically from patients with normal levels.¹⁵⁰ Oligoarticular-onset juvenile idiopathic arthritis is classically considered as not associated with elevated inflammatory markers, although they are present in patients most at risk for developing systemic disease.¹⁵¹

PRACTICAL USE OF ACUTE PHASE REACTANTS

When surveyed in the 1990s, rheumatologists were found to use the ESR more than twice as frequently as they did

CRP levels,¹⁵² although ESR reflects many complex, poorly understood changes in the physical and chemical characteristics of blood not associated with inflammation. As indicated earlier, the reference normal values for ESR are unclear. It is well established that mean ESR values increase substantially with age and differ between men and women. Difficulties associated with interpretation of the ESR and an increasingly positive clinical experience with CRP suggest that rheumatologists may benefit from relying more on CRP than ESR testing.¹⁵³ No single ideal test can be used to evaluate the acute phase response, however. The relative virtues of these tests in following patients with RA have been discussed.^{70,154}

Discrepancies between ESR and CRP may result from effects of blood constituents that are not related to inflammation, but that can influence the ESR, as was discussed earlier. In addition, patterns of acute phase protein changes differ in different conditions.⁵ ESR may be markedly elevated in many patients with active SLE, whereas CRP is normal. Undoubtedly, numerous other clinical situations exist in which similar discrepancies occur. Although falsely high ESR has many noninflammatory physicochemical causes (some known, and many unknown), CRP values greater than 1 mg/dL almost invariably reflect a clinically significant inflammatory process. In light of these considerations, many authors believe that several tests, rather than a single test, should be performed and interpreted in their clinical context. It has been suggested that ESR, which is associated with anemia and immunoglobulin levels, may reflect "general severity" in RA, whereas CRP is a better test of active inflammation per se.¹⁵⁵

C-REACTIVE PROTEIN AND HEALTH: ASSOCIATIONS WITH NONRHEUMATOLOGIC CONDITIONS

Although most ostensibly healthy individuals have CRP concentrations of 0.3 mg/dL or less, some have concentrations greater than 1 mg/dL. Such minor CRP elevation has long been attributed to trivial tissue injury or to minimal inflammatory processes, such as gingivitis. However, recent data indicate that CRP concentrations between 0.3 and 1 mg/dL have clinical relevance. This has led to an explosion of published literature measuring CRP levels in cardiac, neurologic, neoplastic, pulmonary, and even psychiatric disease.¹⁵⁶⁻¹⁶⁰ The foundation of these investigations is the well-established notion that when a high-sensitivity CRP assay is used, serum CRP levels greater than 0.3 mg/dL indicate increased relative risk of atherogenesis and future myocardial infarction.¹⁶¹ The statistical strength of this association has been shown to be as robust as, but not more robust than, established risk factors such as hypertension, diabetes, and hypercholesterolemia.¹⁶²⁻¹⁶⁴ The primary unanswered questions remain: Why does CRP predict myocardial infarction? Is it a pathogenic mediator itself?

The observation that CRP is associated with many "non-inflammatory" conditions, such as low levels of physical activity, low intake of fruits and vegetables, a variety of other "unhealthy" diets, smoking, hypertension, obesity, sleep deprivation, and low alcohol intake, indicates that classic inflammation does not invariably underlie a

CRP response.¹⁶⁵ Many of these CRP-associated conditions are known to be risk factors for cardiovascular disease, confounding the situation and suggesting that CRP predicts myocardial infarction because of its association with these risk factors. In addition, elevated CRP may not reflect inflammation, but rather a response to the presence of distressed, metabolically disturbed cells.¹⁶⁵ This reverse causation offers a potential explanation of the laboratory result, because atherosclerosis might trigger an elevation in CRP.

Nevertheless, CRP has been known for many years to bind to low-density lipoprotein (LDL) and to activate complement—a potentially proinflammatory response; it has also been detected in atherosclerotic plaques.^{29,166-168} These observations have raised the possibility that CRP may play a direct causal role in coronary heart disease. Proatherogenic effects secondary to CRP injections given to mice, however, may have been caused by contaminants in commercial CRP preparations, not by CRP itself.¹⁶⁹ Because statin drugs lower CRP and LDL, some consider their effects to provide indirect evidence of a causal role of CRP. In the recently published JUPITER trial, patients with normal LDL and elevated CRP were prescribed rosuvastatin 20 mg daily or placebo and were followed prospectively. Those in the treatment arm had significant reductions in major cardiovascular events.¹⁷⁰ However, whether the effects of the study can be solely dependent on CRP reduction remains unclear; alternative explanations have been put forth, including the question of the importance of lowering LDL even among patients with “normal” levels.¹⁷¹ Whether to target CRP levels in cardiovascular disease is an ongoing topic of intense debate.

Because no “CRP inhibitor” drugs are available to directly measure the effect of lowering the protein, recent studies have centered on observing patients with genetic variations that result in different baseline levels of CRP. To date, results have been conflicting with regard to the role that genetically determined CRP levels play in coronary heart disease. However, additional, more robust analyses are ongoing.¹⁷²⁻¹⁷⁶

Epidemiologic studies describing an association of CRP levels with morbidity and mortality in many chronic diseases and even in normal aging have become a “cottage industry.” It is important to remember that these are observational population studies. Although such associations may have broad and intriguing implications, particularly at a societal level, they reflect probabilities; this limits their clinical value when they are applied to the individual patient.

Imaging Modalities in Rheumatic Diseases

MIKKEL ØSTERGAARD •
ROBERT G.W. LAMBERT • WALTER GRASSI

KEY POINTS

Practical Use of Imaging in Inflammatory Joint Diseases

A. Peripheral joints

Use in clinical practice:

- To establish a diagnosis of rheumatoid arthritis (RA): x-ray, magnetic resonance imaging (MRI), ultrasonography (US)
- To assist with the diagnostic workup in suspected, but not definite, inflammatory joint disease and early, unclassified inflammatory joint disease (by detection of presence/absence of synovitis, enthesitis, bone erosions etc.): x-ray, MRI, US
- To monitor disease activity: MRI, US
- To monitor structural joint damage: x-ray, MRI
- To assist with prognostic stratification of patients with early RA: x-ray, MRI, (US*), digital x-ray radiogrammetry (DXR*)
- To help define the presence or absence of imaging remission: MRI, US
- To guide aspirations and injections in joints, bursae, and tendon sheaths: US

Use in clinical research:

- To assess structural joint damage in RA trials: x-ray, MRI
- To assess the anti-inflammatory effectiveness of a new compound MRI, US
- For pretrial selection of patients most likely to progress ("enrichment"): x-ray, MRI

B. Axial joints

Use in clinical practice:

- To establish a diagnosis of ankylosing spondylitis (AS)/axial spondyloarthritis (SpA): x-ray and MRI
- To monitor disease activity: MRI
- To monitor structural joint damage: x-ray, MRI, computed tomography (CT†)

Use in research:

- To assess structural progression AS/SpA trials: x-ray, (MRI*)
- To assess the anti-inflammatory effectiveness of a new compound: MRI
- For pretrial selection of patients most likely to progress: x-ray, MRI

*Promising, but more data needed.

†CT allows this but cannot be used owing to radiation exposure.

by imaging. In rheumatology, imaging may be used for multiple reasons that include establishing or confirming the diagnosis, determining extent of disease, monitoring change in disease (e.g., activity, structural damage), selecting patients for specific therapies (e.g., surgery, injections), identifying complications of disease or treatment, and assessing therapeutic efficacy in trials. These entirely different contexts may favor different imaging approaches.

The present chapter focuses on inflammatory joint diseases, such as rheumatoid arthritis (RA), psoriatic arthritis (PsA), ankylosing spondylitis (AS), other types of axial spondyloarthritis (SpA), gout, and osteoarthritis (OA). Other aspects, including nuclear medicine and capillaroscopy in connective tissue diseases and vasculitides, are also briefly discussed. The reader is kindly referred to the chapters on individual diseases for imaging aspects of other rheumatologic diseases, and to textbooks of musculoskeletal radiology¹ for a more detailed description of the different imaging modalities, including the technical aspects. This chapter outlines the virtues of CR and describes its current major importance in diagnosis and follow-up of rheumatologic diseases, but also, by putting emphasis on newer imaging modalities, particularly MRI and US, stresses that rheumatology has entered a time of exciting and expanding therapeutic and imaging possibilities.

CONVENTIONAL RADIOGRAPHY

KEY POINTS

X-ray is relatively inexpensive, easily available, and reliable.

X-ray provides information on bone damage and, indirectly through joint space narrowing, on cartilage damage, whereas x-ray is neither sensitive nor specific for soft tissue change.

X-ray findings are important parts of the classification criteria for many rheumatic diseases, including RA, AS, SpA, PsA, and OA.

X-ray often should be the first imaging investigation in arthritis because the significance of positive and negative findings is well known.

X-ray can be used to follow structural damage progression in inflammatory and degenerative joint diseases but is less sensitive to change than MRI.

The main disadvantage of x-ray is its low sensitivity, particularly for soft tissue changes.

For decades, imaging in rheumatology has been synonymous with conventional radiography (CR). However, new imaging modalities such as magnetic resonance imaging (MRI) and ultrasonography (US) have dramatically increased the amount and scope of information obtainable

The first roentgen ray image was an “x-ray” of the hand. Since then, imaging of musculoskeletal structures has always been an important role of conventional radiography (x-rays).¹ The simple radiograph is relatively cheap, is available worldwide, and produces images that are almost identical regardless of technical parameters or whether the image is analogue or digital. The reliability of the image means that, despite the limitations of radiography, advances in clinical practice can rely on the good old x-ray, with the knowledge that it is largely independent of technologic advances. For many years to come, radiographs will appear much the same as they do now.

Technical Aspects

The conventional radiograph is a two-dimensional summation image that is dependent on variable absorption of x-rays by different tissues for its inherent contrast. It has a very high spatial resolution that is rarely surpassed by other modalities, but radiography offers high contrast only between a limited number of structures, namely, bone (calcium), soft tissue, and air. Fat is visible as a separate density, but the distinction between soft tissue and fat is often subtle, and radiography cannot distinguish between the other soft tissues because cartilage, muscle, tendon, ligament, synovium, and fluid all appear at the same density. These characteristics give the radiograph its inherent advantages and disadvantages.

In its favor, the x-ray shows skeletal structures very well, and because it is a summation image, it allows excellent overall assessment of skeletal trauma and alignment. The limited number of images produced facilitates rapid review, and the high bone–soft tissue contrast often produces radiographic manifestations of disease in specific patterns that make the test particularly useful in daily clinical practice. The biggest disadvantage of radiography is its inherent lack of soft tissue contrast, which makes it insensitive for the detection of soft tissue abnormalities. The first radiographic sign of inflammatory arthritis may be permanent structural damage (bony erosion); in degenerating joints, cartilage damage is not usually visualized until sufficient overall cartilage loss allows approximation of the bone ends, resulting in “joint space narrowing.”

Although x-rays use ionizing radiation, they should be regarded as relatively safe, especially in older patients. An exception may be spine and sacroiliac joint radiography, for which doses are higher to penetrate the trunk; in a younger population, MRI offers a safer and more informative alternative. In most examinations, two or more projections are required to adequately visualize the joint in question, and radiographic quality is improved by strict adherence to standard imaging protocols.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is the archetypal inflammatory joint disease that primarily targets synovium and peripheral joints. It is a systemic inflammatory disorder in which the typical clinical manifestations are usually symmetric, and the radiographic signs usually follow this pattern. As in all of radiology, the observed distribution of disease is often characteristic of the underlying cause; in RA, the

metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands, the wrists, and the metatarsophalangeal (MTP) joints of the feet are most often involved.^{1,2}

Juxta-articular osteoporosis is a characteristic feature of RA best seen in early disease in small peripheral joints. Later, generalized osteoporosis is usually present and is exacerbated by disuse. Erosion of bone (Figure 58-1) is a characteristic feature of RA and usually appears first at the margins of the joint, where the proliferating synovium lies directly on the surface of the bone between the edge of the cartilage-covered articular surface and the capsular attachment—the “bare areas.” These marginal erosions may be subtle and first appear as disruption of the thin white cortical line, especially at the radial aspect of the metacarpal heads, where they may be seen best on dedicated radiographic projections such as the ball-catcher’s view of the hands. These erosive changes are a good indication of the aggressiveness of the arthritis. In large joints, synovial proliferation may be very severe before bony erosion is detectable on x-ray. This is especially notable in the knee, where pain and swelling due to arthritis and bursitis occur long before erosion. In addition to bare-area erosions, two other types of erosions have been described in RA. *Compressive erosion* refers to remodeling of inflamed and osteoporotic bone with gradual invagination of one bone into another, typified by protrusio acetabuli of the hip (Figure 58-1E). *Surface erosion* of bone may also be seen, usually resulting from inflammation of an adjacent tendon sheath. A typical location for this is at the outer margin of the ulnar styloid process secondary to extensor carpi ulnaris tenosynovitis.

Joint space involvement is characteristic of RA. In many cases, inflammatory processes result in progressive destruction of articular cartilage, which in turn causes the radiographic finding of concentric joint space narrowing. This is usually diffuse in RA because all cartilage is involved at the same time; this feature may allow differentiation from the focal or asymmetric type of joint space loss that occurs with degenerative disorders. Occasionally cartilage destruction precedes synovial erosion of bone. Continued cartilage damage may result in partial or complete fibrous ankylosis, but progression to bony ankylosis is uncommon, although it may occur in end-stage disease in the wrist or midfoot. Subchondral radiolucent areas are common in RA and are often referred to as *cysts*, *geodes*, or *pseudocysts*. They may develop as a result of intraosseous extension of pannus, injury to the bone of any kind, or true intraosseous rheumatoid nodules. Mechanical factors accentuate their development, and very large cystic lesions may be seen in the elbow, femoral neck, or knee, occasionally precipitating pathologic fracture.

Symmetric soft tissue swelling around the small joints of the hands or feet is often the first clinical and radiographic sign of RA. Soft tissue swelling is caused by joint effusion, synovial proliferation, and periarticular inflammation, but the radiographic findings are nonspecific, and x-rays are much less sensitive for such changes than MRI and US. Eccentric soft tissue swelling may be due to adjacent bursitis, tenosynovitis, or rheumatoid nodules. Involvement of tendons and tendon sheaths is common; however, soft tissue changes usually are poorly visualized and are of lesser diagnostic importance.

Figure 58-1 Rheumatoid arthritis (x-ray). **A**, Multiple typical bone erosions are seen (e.g., in triquetrum, pisiform, scaphoid, radius, and ulnar styloid process). Diffuse cartilage loss also is evident in the radiocarpal compartment. **B**, Severe ulnar deviation is present at the metacarpophalangeal joints with extensive erosions. Severe erosion and bony ankylosis are seen in the wrist. **C**, Posterior oblique view of a shoulder shows severe glenohumeral joint space narrowing with marginal erosion and cystic change of the humeral head adjacent to the greater tuberosity (*curved arrow*). Elevation of the humeral head with respect to the glenoid indicates chronic rotator cuff tear. Tapering of the distal end of the clavicle and widening of the acromioclavicular joint (*straight arrow*) are also evident. **D**, Rheumatoid nodules appearing as lobulated subcutaneous soft tissue swellings (*arrows*) at the extensor surface of the elbow and forearm. **E**, Bilateral protrusio acetabuli. The medial acetabular margins protrude into the pelvis. Severe accompanying cartilage loss has occurred. **F**, Ankle with diffuse loss of cartilage space with erosions of the fibula (*arrow and arrowhead*). The hindfoot is in valgus alignment.

Joint malalignment and deformity (see [Figure 58-1](#)) are very common in RA and occur as the result of laxity and disruption of capsule, ligaments, and tendons. These deformities are most characteristic in the hand, wrist, foot, and neck. Note that these malalignments may be transient and can reduce during positioning for radiographs. Late disease is associated with severe deformity, as is seen in arthritis mutilans.

Spine

Cervical spine involvement is common in RA and merits specific attention. It occurs mainly after several years of disease in rheumatoid factor–positive patients with severe peripheral RA and may cause severe pain, instability, and, ultimately, spinal cord compression.³ Prevalences of radiologic cervical involvement up to 70% have been reported but are much lower in recent studies in accordance with the fact that intensive disease-modifying antirheumatic drug

(DMARD) therapy has been shown to reduce cervical radiologic progression.⁴

The upper cervical region is most affected, although abnormalities throughout the cervical spine are frequent ([Figure 58-2](#)). Upper cervical changes include odontoid process (dens) erosion and atlantoaxial subluxations (anterior, vertical [known as cranial settling], lateral, and posterior); subaxial manifestations include abnormalities of apophyseal and discovertebral joints, subluxation, and dislocation.

Adequate radiographic evaluation of the cervical spine requires lateral views in flexion and extension and should be performed in all RA patients with neck pain. Flexion-extension views are especially important for demonstration of the degree of atlantoaxial instability.

Atlantoaxial subluxation is caused by laxity or rupture of the transverse ligament. The characteristic finding is anterior subluxation (i.e., abnormal separation between the anterior arch of the atlas and the odontoid process of the

Figure 58-2 Cervical spine in rheumatoid arthritis (RA) (x-ray). **A** and **B**, Anterior atlantoaxial subluxation in RA. **A**, Lateral x-ray in flexion shows severe anterior atlantoaxial subluxation with a wide anterior atlantodental interval (*asterisks*) and a decreased posterior atlantodental interval (*arrow*). **B**, Almost complete reduction of subluxation is noted on the lateral view in extension. There also is subaxial subluxation at the level of C4-C5 (*arrowhead*) with erosive changes in various facet joints. O, odontoid. **C**, T2-weighted sagittal magnetic resonance (MR) image in RA shows low signal peri-odontoid pannus (P). The odontoid process appears irregular secondary to erosions (*arrow*). The atlantodental distance shows mild widening (*solid line*). There also is vertical subluxation without signs of cord compression. The anterior subarachnoid space is compromised by disk protrusions at multiple levels. Small erosions (*arrowheads*) are seen at the vertebral end plates at the C6-C7 level.

axis). Reports of the exact lower limit of abnormal distance vary, but a distance greater than 2.5 mm is considered abnormal, as is distance that changes significantly between flexion and extension.¹ Cranial settling is diagnosed by radiographic measurement of the relationship between the tip of the odontoid process and landmarks at the base of the skull.¹ It may lead to protrusion of the dens through the foramen magnum and compression of neurologic structures. Significant atlantoaxial subluxations may require surgery.

Subaxial involvement is frequent and manifests as varying degrees of bone erosion, joint space narrowing, and subluxation of facet joints, as well as disk space narrowing and spinous process erosion. Subaxial subluxations may also lead to neurologic deficits.¹

MRI is useful for providing supplementary information on cervical spine involvement (Figure 58-2C), including spinal cord compression (see MRI section).

Use in Diagnosis, Monitoring, and Prognostication

Diagnosis. Characteristic x-ray findings are part of the American College of Rheumatology (ACR) 1987 classification criteria for RA.⁵ X-ray also has a role in the recent ACR/European League Against Rheumatism (EULAR) 2010 classification criteria, in that patients who display bone erosions typical of RA plus at least one clinically swollen joint fulfill the criteria for and are classified as having RA.⁶ X-ray can be helpful in differentiating RA from

other joint conditions such as osteoarthritis, psoriatic arthritis, and neoplasm.²

Monitoring. In routine clinical management and in clinical trials of RA, x-ray evaluation focuses on joint space narrowing and bone erosion in hands, wrists, and forefeet as measures of structural joint damage.⁷⁻⁹ Validated scoring methods for radiologic damage (the Larsen method and the Sharp method and their modifications) are available and are used extensively in clinical trials.⁸⁻¹⁰ The van der Heijde and Genant modifications of the Sharp score are generally considered the methods that are most sensitive to change, but they are also the most time-consuming.¹¹ For clinical practice, the less time-consuming *simple erosion narrowing score* (SENS), derived by counting joints with bone erosion and joints with joint space narrowing, is available^{12,13} but is seldom used.

Prognostication. Early bone erosion correlates with poor long-term radiographic and functional outcomes,¹⁴ and early progression in x-ray erosion is related to future impairment in physical function.¹⁵ In early undifferentiated arthritis, the presence of x-ray erosion increases the risk of developing persistent arthritis.¹⁶ However, radiographic erosions are present in only a minority of patients with early RA, with prevalences of 8% to 40% at 6 months,¹⁷⁻²¹ and the absence of erosion in early disease is not necessarily associated with good outcomes. Therefore at this stage, x-ray is not effective for identifying future “nonprogressors” (i.e., patients who will not show increasing structural joint damage).²²

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is the archetypal inflammatory joint disease that primarily targets fibrocartilage and the axial skeleton. Cartilaginous joints and sites of entheses (tendon and ligament insertion) are involved early, and the characteristic involvement of the axial skeletal includes a predilection for the sacroiliac joints and all articulations and entheses of the spine.

Sacroiliac Joints

Erosion and ankylosis of the sacroiliac (SI) joints are the hallmarks of spondyloarthritis.^{1,23} Sacroiliitis is usually the first manifestation and is characteristically bilateral and symmetric in AS.^{24,25} Early radiographic findings predominate on the iliac side of the cartilage compartment, with erosion of subchondral bone causing loss of definition of the articular surfaces, usually accompanied by variable degrees of adjacent osteoporosis and surrounding reactive sclerosis. Bone erosion may result in the radiographic observation of focal joint space widening (Figure 58-3A), and as the disease progresses, the definition of the joint is completely lost with radiographic superimposition of erosion, sclerosis, and new bone formation, which fills in the erosions and the original cartilaginous “joint space.” The joint may disappear completely in late disease with ankylosis and remodeling of the bone (Figure 58-3B). The ligamentous compartment of the SI joint is frequently affected by bony erosion and enthesal proliferation, although these may be difficult to see radiographically.^{24,25}

Spine

Traditional descriptions of the initial sites of spinal involvement are enormously influenced by the inability of radiography to adequately visualize many parts of the spine. Radiographic reports indicate that the lumbosacral and thoracolumbar junctions are first affected, whereas the MRI literature clearly indicates a predilection for early involvement of the midthoracic spine—an area that is extremely difficult to evaluate radiographically. The cervical spine is rarely affected first, but this can occur occasionally in women, and spinal disease rarely occurs in the absence of significant SI joint involvement.

Early radiographic manifestations of AS in the spine are most often due to enthesitis at the edges of the discovertebral joints.²⁴ Focal sclerosis (the “shiny corner”) and erosion (the “Romanus lesion”) develop at the attachment of the annulus fibrosus to the anterior corner of the vertebral end plate and are characteristic features of early AS (Figure 58-4A).²⁶ The anterior borders of the vertebrae may appear straight or “squared” owing to periosteal proliferation of new bone filling in the normal concavity or erosion at the anterosuperior and anteroinferior vertebral margins. This observation is much easier to make in the lumbar spine, where normal vertebrae are always concave anteriorly in comparison with the thoracic and cervical spine, where the normal contour is much more variable and may be square or occasionally convex.

The hallmark of spinal disease in AS is the development of characteristic bony spurs known as *syndesmophytes* (see Figure 58-3C). These start as thin, vertically oriented

Figure 58-3 Ankylosing spondylitis (x-ray). **A**, Sclerosis (arrows) is seen along the iliac sides of the sacroiliac joints, along with loss of portions of the iliac subchondral bone indicating erosion. **B**, Bilateral hip joint space narrowing is present. A ring of osteophytes is noted at the synovial insertion (arrows) on each femoral head. The sacroiliac joints are fused (ankylosis). **C**, Syndesmophytes (black and white arrows), some of which extend from the edge of one vertebral body to the next (bridging syndesmophytes, ankylosis; black arrows), are seen in this lateral view of the spine.

Figure 58-4 Ankylosing spondylitis (x-ray and magnetic resonance imaging [MRI]). **A**, Lateral x-ray of the spine shows that marked erosion at the vertebral margins has produced straight or slightly convex anterior vertebral surfaces (“squaring”). New bone formation has resulted in “shiny corners” (arrows) and contributes to vertebral body squaring. The facet joints are fused. **B**, Sagittal fast spin echo T2-weighted magnetic resonance (MR) image in another patient shows bone marrow edema at the anterosuperior corners of the vertebral bodies (arrows), corresponding to early osteitis. **C** and **D**, Fracture in ankylosing spondylitis. **C**, X-ray shows disruption of the previously fused C6-C7 facet joints (arrow) and slight anterior subluxation. **D**, Sagittal T2-weighted MR image confirms a high signal fracture line (arrow) through the superior aspect of C7.

projections of bone that develop as the result of ossification within the outer fibers of the annulus fibrosus of the intervertebral disk. Syndesmophytes are radiographically visible on the anterior and lateral aspects of the spine, starting from the corner of the vertebra. Progressive growth will bridge the intervertebral disk causing ankylosis, and extensive syndesmophyte formation produces a smooth, undulating spinal contour—the “bamboo spine.” The syndesmophytes that characterize AS must be differentiated from other spinal and paraspinal bone formations. Degenerative bony spurring in spondylosis deformans arises several millimeters from the discovertebral junction, is typically triangular in shape, and has a horizontally oriented segment of variable length

at the point of origin. In diffuse idiopathic skeletal hyperostosis (DISH), bone formation in the anterior longitudinal ligament results in a flowing pattern of ossification that is usually thick, and the sacroiliac joints are not involved.

Erosion of the vertebral end plate is common in later stages of ankylosing spondylitis and may be focal or diffuse. It is also seen when pseudoarthrosis develops following a fracture in a previously ankylosed spine. Changes in the apophyseal joints are common and start with ill-defined erosion and sclerosis, but they may be difficult to see. Capsular ossification or intra-articular bony ankylosis frequently occurs in late disease (see Figure 58-4). The ankylosed spine is highly susceptible to fracture (Figure 58-4C and D), which should always be suspected in cases of unexplained pain exacerbation. Enthesitis at the interspinous and supraspinous ligamentous attachments is very common with bone formation, causing whiskering and interspinous ankylosis.

Use in Diagnosis, Monitoring, and Prognostication

Although the modified New York criteria are actually classification criteria, they are the most commonly used criteria for the diagnosis of AS and are based on clinical features and radiographic sacroiliitis.²³ According to these criteria, AS may be diagnosed if, in addition to the presence of one clinical criterion, grade 2 sacroiliitis (minimal sacroiliitis: loss of definition of the joint margins, minimal sclerosis, joint space narrowing, and erosions) or higher occurs bilaterally, or grade 3 (moderate sacroiliitis: definite sclerosis on both sides of the joint, erosions, and loss of joint space) or grade 4 (complete bony ankylosis) occurs unilaterally.²³ Owing to the requirement for these radiographic structural changes, the median duration of disease before diagnosis has been 7 to 10 years.²⁷ Definitions of radiographic changes according to the New York criteria are included in the Assessment of Spondyloarthritis International Society (ASAS) classification criteria for axial spondyloarthritis,²⁸ the European Spondyloarthritis Study Group (ESSG) criteria for spondyloarthritis,²⁹ and the modified New York criteria.²³

Radiography of the spine is not included in the classification criteria but may be useful for following structural disease progression in patients with spinal involvement. Bone changes seen in patients with axial SpA develop slowly and often are not present in patients with early disease; generally, only minor changes can be observed in 1 to 2 years. Different scoring methods, all based on assessment of lateral views, have been developed to quantify changes in the spine of patients with AS—the Stoke AS Spine Score (SASSS), the Bath AS Radiology Index (BASRI), and the modified Stoke AS Spine Score (mSASSS). A comparative study of these three methods concluded that all measures were reliable, but that mSASSS was more sensitive to change.³⁰ These spine scores are used primarily in clinical research.

Psoriatic Arthritis

The presentation of psoriatic arthritis (PsA) is quite variable but is often distinctive. Peripheral joint involvement is common, and up to half of patients with PsA have

evidence of joint damage on radiographs within 2 years of presentation.³¹ The hand and the wrist are most often involved and are affected in up to three-quarters of patients with PsA, but the pattern of joint involvement varies from patient to patient and over time in the individual patient. Radiographic appearances are usually asymmetric and may have a ray distribution, with affected joints involving a single digit, including the distal interphalangeal (DIP) joints (Figure 58-5), which are seldom involved in RA. Clinically, this manifests as dactylitis and is a common early presentation of PsA. Osteoporosis is frequently absent, and a distinguishing feature of PsA is the propensity for bone proliferation. This may be seen in the form of periostitis of the shafts of the phalanges, which is sometimes the first radiographic manifestation, or irregular bony spurring at joints or entheses. Fluffy new bone formation adjacent to marginal joint erosions may result in a particularly characteristic “whiskering” appearance. Severe marginal erosion of the heads of metacarpals or phalanges may produce the appearance of a whittled pencil; if combined with deep central erosion of phalangeal bases, this may be referred to as the “pencil-in-cup” appearance. Ankylosis of joints occurs frequently in advanced disease. Large joints are less often affected, and the findings are usually similar to those of RA. Spinal involvement is frequent in PsA. It may be seen in early disease, and sacroiliitis may be demonstrable in up to 75% of patients.³² Changes may be extensive and are more likely to be asymmetric than in AS.

Use in Diagnosis, Monitoring, and Prognostication

Although RA is characterized mainly by osteodestructive lesions, in PsA osteodestructive and osteoproliferative manifestations may coexist not only in the same patient, but even in the same joint.³³ In particular, osteoproliferative

lesions on radiography are characteristic and are included in the new classification criteria (CASPAR) for PsA.³⁴ The presence of juxta-articular new bone formation, which appears as ill-defined ossification near joint margins (but excluding osteophytes) on radiographs of the hand or foot, is one of five criteria.³⁴

Structural joint damage on conventional radiography is an important outcome measure in PsA. Different radiographic scoring methods of peripheral joints have been developed (e.g., the Sharp-van der Heijde modified scoring method for PsA, which is a detailed scoring system for evaluating erosion and joint space narrowing), and osteolysis and pencil-in-cup phenomena are assessed separately.¹¹ Scoring systems are used primarily in clinical trials. No specific scoring systems are available for spine and sacroiliac joints in PsA; these areas can be monitored as in AS (see later).

Gout

A variety of microcrystals can deposit in and around the joints, inducing an inflammatory response. In this chapter, the characteristics of gout (i.e., arthritis related to monosodium urate deposition) and of calcium pyrophosphate dihydrate (CPPD) crystal deposition disease will be presented. The reader is referred to chapters on individual diseases for descriptions of the remaining conditions, such as calcium hydroxyapatite crystal deposition disease, hemochromatosis, ochronosis, and Wilson's disease.

Radiography is not helpful in the diagnosis of acute gouty arthritis because findings are limited to the soft tissues and are nonspecific. Chronic tophaceous gout is an asymmetric arthritis that frequently affects the feet, hands, wrists, elbows, and knees. The most common site of involvement is the first metatarsophalangeal (MTP) joint (Figure 58-6).

Figure 58-5 Psoriatic arthritis (x-ray). **A**, Distal interphalangeal joint with classic radiographic findings, including soft tissue swelling, bone erosions with accompanying bone proliferation, and lack of osteoporosis. **B**, Arthritis mutilans resulting from psoriatic arthritis with destructive changes and joint deformity of the hand and pancompartmental ankylosis of the wrist. **C**, Psoriatic spondylitis. Thick asymmetric paravertebral ossifications (arrows), which are characteristic of psoriatic spondylitis and reactive arthritis. (From Resnick D, Niwayama G: *Diagnosis of bone and joint disorders*, Philadelphia, 1988, WB Saunders.)

Figure 58-6 Tophaceous gout (x-ray, computed tomography [CT], and magnetic resonance imaging [MRI]). **A**, X-ray of forefoot in tophaceous gout. Extensive bone destruction is seen at the first metatarsophalangeal (MTP) joint with overhanging edges (*arrowhead*) and soft tissue swelling. Smaller erosions are present involving the first tarsometatarsal and second MTP joints (*arrows*). **B**, CT scan shows hyperdense tophus around the extensor digitorum muscle (*arrow*), with smaller deposits around the other extensor tendons. Axial precontrast (**C**) and coronal short tau inversion recovery (**D**) MR images show a large tophus (*arrow*) medial to the first metatarsal bone. Ca, calcaneus; Na, navicular. (**C** and **D** Courtesy Professor Fiona McQueen, Auckland, New Zealand.)

Radiologic changes in long-standing gout are related to tophi and their effects on soft tissue and bone.³⁵

Tophi appear as eccentric, nodular soft tissue masses around the joints with an amorphous increased density or patchy calcification.³⁵ Intraosseous tophi cause well-marginated subchondral cystic lucencies or intraosseous calcifications. Erosion of adjacent bone is common at the periosteal or endosteal surface. Erosions may be intra-articular, para-articular, or remote from the joint and typically are well defined with smooth sclerotic borders. An overhanging margin of bone at the edge of the erosion is a characteristic feature of gout. The joint space and bone density are usually preserved until late in the disease. Bursal inflammation commonly produces soft tissue swelling around the olecranon and in a prepatellar location.

Use in Diagnosis, Monitoring, and Prognostication

The 1977 Criteria for the Classification of Acute Arthritis of Primary Gout³⁶ include the conventional radiographic features of asymmetric swelling and subcortical cysts without erosion. However, conventional radiographic features of acute gout have low clinical utility owing to lack of sensitivity and specificity. In the chronic phase, the characteristic pattern with asymmetric, erosive polyarticular disease and tophi appearing as nodular soft tissue masses with amorphous increased density or patchy calcification may be diagnostically useful.

A specific gout radiographic scoring method has been developed and validated and may improve sensitivity to change in longitudinal studies.³⁷ However, radiography is

not a sensitive method for monitoring gout manifestations, compared with US and MRI, because inflammatory changes and tophi volumes cannot be assessed.³⁸

Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

The term *CPPD crystal deposition disease* refers to a variety of clinical situations, including asymptomatic crystal deposition, pseudogout, pyrophosphate arthropathy, and other, less frequent presentations, such as pseudo-RA. *Chondrocalcinosis* is a general term that refers to calcification of hyaline or fibrocartilage regardless of its origin (Figure 58-7).

An acute attack of pseudogout is often a monoarthropathy, and typical radiographic findings of soft tissue swelling and joint effusion are nonspecific, mimicking gout and infection. Often chondrocalcinosis is not radiographically visible. X-ray changes in more chronic pyrophosphate arthropathy are very similar to those in OA, with joint space narrowing, sclerosis, and subchondral cysts, with or without intra-articular or periarticular calcinosis.³⁹

The patellofemoral, radiocarpal, and second and third MCP joints are typical sites of involvement in pyrophosphate arthropathy. Distribution is usually bilateral and may be symmetric. In addition to the usual target sites, arthritic changes may be observed in non-weight-bearing joints and sacroiliac joints.⁴⁰

Pyrophosphate arthropathy may be associated with extensive and rapid subchondral bone collapse and fragmentation with intra-articular loose bodies, resembling neuropathic osteoarthropathy (pseudo-Charcot). Tumorous CPPD crystal deposits that resemble gouty tophi are observed occasionally, most frequently in digits, and are referred to as *tophaceous pseudogout*.⁴¹

Septic Arthritis

Septic arthritis usually is monoarticular and typically is associated with rapid onset of symptoms, systemic illness,

obvious local clinical signs, and laboratory evidence of acute inflammation. The earliest clinical sign is symmetric soft tissue swelling around a joint due to soft tissue edema, hypertrophied synovium, and joint effusion. However, this may be difficult to discern on x-ray, and periarticular osteopenia may be the first radiographic feature. Initial widening of the joint space may be seen, as in septic arthritis of the pediatric hip. Marginal erosions develop quickly and have a very similar appearance to other forms of erosive inflammatory arthritis. As the infection progresses, hyaline cartilage and the subchondral cortex are rapidly destroyed, with progressive narrowing of the joint space (Figure 58-8). In late stages, ankylosis of the joint may be seen. Adjacent osteomyelitis occurs with increasing frequency as the infection becomes chronic. With granulomatous infection, the characteristic triad (Phemister's triad) of radiographic findings consists of marked osteoporosis, marginal erosions, and absent or mild joint space narrowing. Periostitis and bone production are less common.

Use in Diagnosis, Monitoring, and Prognostication

Radiography should be performed routinely but is insensitive for diagnosis. When clinical suspicion of septic arthritis arises, joint aspiration should be performed without delay.

The utility of radiography is limited in septic arthritis, and immediate joint aspiration (directly or by image-guided techniques) is required for early diagnosis; more advanced imaging techniques are required for assessment of associated osteomyelitis or other complications.⁴² However, radiography still should be routinely performed because it may assist in interpretation of other studies and offers a satisfactory overall assessment of bone morphology and background disease.

Osteoarthritis

Osteoarthritis (OA) primarily targets hyaline cartilage, and its distribution is profoundly influenced by mechanical

Figure 58-7 Calcium pyrophosphate dihydrate crystal deposition disease (x-ray and magnetic resonance imaging [MRI]). X-ray of the knee (**A**) shows linear calcification within the lateral meniscus, whereas sagittal proton density MRI (**B**) of the same patient shows increased signal within the lateral meniscus, corresponding to chondrocalcinosis. **C**, X-ray of forefoot shows cartilaginous and capsular calcifications (arrows) within the second through fourth metatarsophalangeal joints. A nondisplaced fracture of the fourth metatarsal neck is noted.

Figure 58-8 Septic arthritis (x-ray and magnetic resonance imaging [MRI]). **A**, X-ray in anteroposterior view of sacroiliac joints shows destruction of the right sacroiliac joint as part of septic arthritis (arrows). **B**, In another patient, short tau inversion recovery (STIR) coronal MRI through sacroiliac joints shows erosive changes in the right sacroiliac joint with extensive bone marrow edema. **C** and **D**, Tuberculous spondylitis. **C**, X-ray of the lumbar spine in lateral view shows disk space narrowing at the L3-L4 level with destructive changes involving the superior end plate of the L4 vertebral body (arrow). **D**, Coronal STIR MRI of the lumbar spine of the same patient confirms focal destruction of the L4 vertebral body (arrow). Enlargement of both psoas muscles (P) with increased signal is noted, owing to paraspinal extension of the infection.

factors. OA is typically asymmetric in distribution both within and between joints. The most characteristic sites of osteoarthritis include hips, knees (Figure 58-9), proximal and distal interphalangeal joints of the hand, first carpometacarpal and trapezioscapoid joints of the wrist (Figure 58-10), and first metatarsophalangeal joints.¹

Joint space narrowing due to thinning of hyaline cartilage is a key feature of OA. Unlike the inflammatory arthropathies, resultant narrowing of the radiographic joint space is asymmetric, with cartilage thinning more pronounced in areas subject to greater mechanical stress, such as one compartment of the knee. Accurate assessment of cartilage loss is hugely influenced by radiographic

projection, particularly in the lower limbs. Sensitive detection of cartilage thinning requires apposition of the most affected surfaces, which requires the joint to be optimally positioned with sufficient mechanical stress to bring the surfaces into contact. In the knee, for example, angular deformity tends to reduce on supine radiography, and severe cartilage loss may not be detected at all (see Figure 58-9). Bilateral weight-bearing projections are more consistent for the detection and measurement of cartilage loss, and the erect extended anteroposterior (AP) view has been established as the preferred projection for diagnostic utility. However, no view is completely reliable until global loss of cartilage occurs in late disease. Weight bearing in flexion is

Figure 58-9 Osteoarthritis of the knee (x-rays). Non-weight-bearing x-rays of the knee frequently underestimate the severity of cartilage loss. A 59-year-old man with pain and suspected osteoarthritis had supine anteroposterior (AP) (A) and erect weight-bearing AP (B) x-rays of the knee. The supine view demonstrates mild osteophytosis and possible subtle joint space narrowing in the medial compartment, whereas on the weight-bearing view, severe medial joint space narrowing is present, indicating severe cartilage damage (arrow). Usually the weight-bearing semi-flexed view is most sensitive to joint space narrowing (cartilage loss), but this is unpredictable. In a 53-year-old man, the erect AP view (C) shows more severe joint space narrowing (arrow) than is seen on the weight-bearing semi-flexed view (D).

the most sensitive projection for cartilage thinning in the knee and is most reliable for detection of change, although the ideal degree of flexion for a specific individual varies according to the distribution of cartilage loss (see Figure 58-9).^{43,44}

Osteophytes, the most characteristic abnormality of OA, are more specific than joint space narrowing and often are the first radiographic sign of the disease. They start as osseous metaplasia of the hyaline cartilage best seen at the articular margins but also occur centrally on the articular surface. They can become large and often dominate the

radiographic appearance. Thus, osteophytes are the key criterion in defining the presence of OA.⁴⁵

Bone density is usually normal or sclerotic. Bone erosion does not occur, except at the articular surface in late disease and occasionally earlier in the interphalangeal (IP) joints in inflammatory OA. The radiographic appearance of peri-articular soft tissues is relatively normal in OA. Synovitis and effusion do occur but only rarely dominate the radiographic presentation.

Some deformity is common but tends to occur in particular joints such as the thumb and the knee. The deformity is

Figure 58-10 Osteoarthritis of the hand (x-ray and magnetic resonance imaging [MRI]). **A**, X-ray shows asymmetric cartilage space narrowing at the proximal and distal interphalangeal joints, the first carpometacarpal joints, and the scaphoid-trapezium-trapezoid articulations. Subluxation at the first carpometacarpal joint and secondary hyperextension at the metacarpophalangeal joints are characteristic deformities of osteoarthritis. **B**, “Gull wing” deformities in erosive osteoarthritis: Cartilage loss and bone remodeling at the third and fourth proximal interphalangeal joints produce a gull wing appearance. X-ray (**C**) and coronal MRI (**D**) of distal interphalangeal joint show osteophyte and central erosions/collapse of the bone plate, representing severe osteoarthritis. (**C** and **D** Courtesy Dr. Ida Haugen, Oslo, Norway.)

due primarily to asymmetric loss of cartilage and bone, resulting in malalignment or subluxation.

Use in Diagnosis, Monitoring, and Prognostication

Conventional radiography is the standard method for diagnosis and follow-up of OA. Radiographic changes are essential in the ACR criteria for classification of OA. A patient with radiographic osteophytes, knee pain, and age above 50 years, stiffness for less than 30 minutes, or crepitus should be classified as having OA.⁴⁵ However, newer imaging modalities, in particular MRI, are providing additional information, which can be used in clinical trials and in enhancing our understanding of the disease.

Various scoring systems have been developed to grade the severity of OA. Among the most well known is the Kellgren and Lawrence five-point scale, which has been used widely in OA research studies.⁴⁶ Atlas-based scoring systems have been developed that provide more accurate discrimination between individual radiographic features of OA.^{46,47} However, whichever system is used, the reliability is variable. In addition, quantitative measurement of joint space width as a surrogate for cartilage thickness has been employed in research studies, particularly in cases of knee OA, but also in hip and hand OA.

COMPUTED TOMOGRAPHY

KEY POINTS

CT is a tomographic radiographic imaging technique that visualizes calcified tissue with high resolution. CT is a standard reference for detecting bone destruction.

In rheumatology, CT is useful mainly for detection of bone abnormalities in the axial skeleton (e.g., erosion, sclerosis, new bone formation, fracture).

CT is more sensitive for these purposes than x-ray and on most occasions MRI.

The role of CT of the axial skeleton is limited by a relatively large amount of ionizing radiation.

In practice, CT is rarely used unless x-ray is unclear and MRI is unavailable.

The main disadvantages of CT are the low sensitivity for soft tissue changes and the high exposure to ionizing radiation.

Computed tomography (CT) has been available for 40 years, and each decade has brought continued development in computing and engineering, resulting in remarkable changes in the technology. Although still limited in terms of soft tissue contrast, CT offers fast and reliable acquisition, high resolution, and multiplanar capabilities, which have enhanced its use in recent years. The modern CT scanner is a remarkable tool that might have an increasingly important role in arthritis imaging in the future.

Technical Aspects

CT image acquisition is no longer restricted to the axial plane of imaging, and its multiplanar capability is so versatile that many CT scans of the body are now interpreted primarily from coronal or sagittal images in the same way as MRI. Data acquisition is so fast that patient motion is rarely a problem because CT scans are now routinely acquired in a few seconds. In fact, CT is often faster than taking multiple radiographs. Complex requirements for

patient positioning in musculoskeletal CT are now largely irrelevant in that almost all studies can be reconstructed to eliminate positioning problems. Patient tolerance is excellent and, unlike with MRI, no absolute contraindications to CT are known. Spatial resolution is high, usually higher than that of MRI, and contrast resolution between soft tissue and bone is unsurpassed by any other modality. However, despite all the advantages just listed, applications of CT in arthritis imaging will remain somewhat limited. CT still has two fundamental flaws that prevent its universal application. First, CT is constrained in the same way as radiography by its limited soft tissue contrast capability. Second, ionizing radiation is used (with increasing dose proportional to the size of the body part and the requirements for spatial detail).

Although this is not a problem with the more distal extremities because the exposure doses are smaller and the tissue more radioresistant, it remains an issue for spine, hip, and shoulder CT. Consequently, in most routine clinical situations, radiography provides sufficient information of a similar nature as CT for clinical decision making, and x-ray is cheaper than CT and is readily available; ultrasonography is a better and cheaper way to visualize and quantify superficial soft tissue pathology, and MRI offers superior soft tissue contrast and bone marrow imaging.

Rheumatoid Arthritis

The exquisite inherent contrast between bone and soft tissue that is afforded by CT makes it a gold standard reference for the detection of bone erosion; as such, CT is ideally suited to the investigation of erosion in inflammatory arthritides. Modern CT with isotropic voxel acquisition and three-dimensional visualization allows accurate detection and quantification of bone erosion with good intraobserver agreement, whereas radiography is limited by its two-dimensional projection and superimposition of structures. However, CT is very limited in its ability to visualize soft tissue changes, and even with contrast enhancement and complex subtraction techniques, CT remains inferior to MRI and ultrasound for assessment of synovial changes such as thickening and hyperemia. Furthermore, detection of erosion on CT and MRI shows very good agreement generally, although CT is slightly more sensitive.^{48,49}

Use in Diagnosis, Monitoring, and Prognostication

CT is not currently used in routine clinical practice for the diagnosis of RA. However it could be useful for diagnosis in that CT appears to be the most sensitive technique for detection of erosion,^{48,49} and CT of the feet is very simple with a very low radiation dose. CT is used for problem solving in specific cases, such as in examination of the cervical spine if MRI is unavailable or contraindicated.

Use of CT for longitudinal assessment of damage progression has potential merit.^{49,50} A problem with CT in comparison with MRI or US is its inability to demonstrate improvement in soft tissue pathology. No CT data are available for prognostication in RA. Current use of CT in RA is very limited, although its ability to define erosion so clearly offers opportunities for future developments in early diagnosis and clinical trial research.

Figure 58-11 Bone erosion in sacroiliac joints in spondyloarthritis (computed tomography [CT]). Coronal (A) and axial (B) CT images of the sacroiliac joints in a patient with spondyloarthritis. Bone erosions (white arrows) and mild sclerosis and new bone formation (black arrows) are seen.

Ankylosing Spondylitis/Axial Spondyloarthritis

CT allows visualization of the same pathologic processes as conventional radiography—erosion, osteoporosis/sclerosis, and new bone formation/ankylosis—with the added benefit of multiplanar imaging free from superimposition of overlying structures (Figure 58-11).

In AS, the pathologic processes start in the bone marrow and at sites of entheses. However, CT has poor ability to detect soft tissue change and is usually normal until structural damage is present. CT can detect osteoporosis or osteosclerosis quite well, but these changes are very nonspecific. The primary value of CT in AS involves its ability to detect and clearly define erosion of bone at any joint or entheses. New bone formation is also well visualized in the form of syndesmophytes, ligamentous ossification, and peri-articular and intra-articular ankylosis, but use of CT in this regard is limited. CT can show these findings equally well in the axial and peripheral skeleton but is used primarily in areas where radiographic visualization or interpretation is problematic.

Use in Diagnosis, Monitoring, and Prognostication

Diagnosis. The diagnosis of AS is based primarily on the radiographic observation of bilateral moderate or unilateral severe sacroiliitis. When good quality radiographs of the sacroiliac joints are normal or radiographic changes meet diagnostic criteria, CT has no role. Early detection of AS is better investigated by MRI, and if clearly defined structural damage is present on x-ray, CT has no additional diagnostic utility. However, CT of the sacroiliac joints is much easier to interpret than radiography, which is notoriously subject to poor observer reliability. When radiographic findings are

unclear, CT will usually resolve this uncertainty. Because CT shows bone erosion in exquisite detail, it may have a role to play in the further investigation of equivocal MRI findings. It should be noted that classification criteria for AS depend on radiographic findings and more recently MRI but not CT specifically. In the spine, CT is useful in the diagnosis of complications of late disease such as spondylodiskitis or spinal fracture when patients may be unable to tolerate MRI because of pain or spinal deformity.

Monitoring Disease Activity and Damage. CT has no useful role in monitoring disease activity or damage. CT cannot show active inflammation, and the relatively high radiation dose of CT precludes its routine use for assessment of damage progression.

Prognostication. The prognostic value of CT findings of sacroiliitis requires further investigation.

Psoriatic Arthritis

CT is rarely used for the investigation of PsA, and very few data have been published on this topic. In the peripheral skeleton, it would be expected that the application of CT for PsA would be similar to that for RA, and in the axial skeleton, use of CT would be similar to that for AS. In both cases, use of CT is limited by an inability to directly visualize inflammation in bone or soft tissue, and although it likely has superior ability versus radiography in detecting bone erosion or proliferation, in most circumstances the extra radiation dose is not warranted.

Use in Diagnosis, Monitoring, and Prognostication

CT visualizes bone erosion and bone proliferation, but no systematic studies of specific diagnostic utility or prognostic value have been performed. Because of radiation concerns, CT is not used for disease monitoring in PsA.

Gout

CT allows clear visualization of bone erosion, and recent developments in technology offer exciting prospects for crystal imaging.

Acute and chronic tophaceous gout is associated with deposition of urate crystals in soft tissues and the development of tophi. Chronic tophi are often partially calcified, and all CT scanners are sensitive for the deposition of calcium in soft tissues (see Figure 58-6). The condition frequently involves intraosseous deposition of crystals, which is much better visualized on CT than on radiography.⁵¹ CT shows quite well soft tissue swelling due to tophi, and because anatomic bone detail is very good on CT, erosions are clearly delineated. Dual-energy CT is a new technologic development whereby images can be reconstructed based on a two-material decomposition algorithm that can separate calcium from monosodium urate (Figure 58-12).⁵²

Use in Diagnosis, Monitoring, and Prognostication

CT visualizes bone erosions and tophi, but no systematic studies of specific diagnostic utility have been performed. Until recently, CT had no role in the diagnosis of acute gout before the development of bone erosions or tophi because

it does not provide imaging of synovitis, tenosynovitis, or osteitis. However, CT scanning with dual-energy acquisition is a recent technical development that appears to offer accurate detection of the presence of monosodium urate and likely will have an important role in diagnosis and research where available.

CT is reliable for monitoring tophus size.^{38,53} A bone erosion scoring method has recently been developed.⁵⁴ These methods may be useful in trials.

Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

CT is not used in the management of uncomplicated peripheral CPPD, although calcifications can be visualized. CPPD can involve the cervical spine and may cause neck pain. In such patients, CT may visualize CPPD deposition at the craniovertebral junction, often in the transverse ligament of the atlas (crowned dens syndrome).^{55,56} Calcific deposits may also be found in other periodontoid structures and in the ligamenta flava in some patients, as may osseous abnormalities of the odontoid process such as subchondral cysts or erosions. CT may also be used for verifying the presence of calcifications at other rare locations (e.g., the temporomandibular joints).⁵⁷

Septic Arthritis

CT is rarely used for the investigation of septic arthritis. Acute septic arthritis of large joints is a surgical emergency, and although x-ray, fluoroscopy, and ultrasound may be useful for diagnosis or for image-guided aspiration, no use for CT in the peripheral skeleton is known. In chronic septic arthritis and infectious diskitis, CT may be used to investigate complications, particularly osteomyelitis. However MRI or a variety of scintigraphic studies are generally preferred.⁴² In complex cases where MRI scanning is problematic, contrast-enhanced CT can be very useful in detecting abscess formation in deep soft tissues that are not easily assessed by ultrasound. CT guidance may be preferred for spine biopsy as well.

Osteoarthritis

Even though CT can detect bone changes such as osteophytes more accurately than x-ray,⁵⁸ overall it offers little additional diagnostic utility in peripheral joints. It generally has poor soft tissue contrast capability, hyaline cartilage cannot be directly visualized, and spatial resolution of bone detail is inferior to that of radiography. It can be used in specific problem-solving situations where anatomy is complex and/or poorly visualized on x-ray, such as in the lumbar spine facet joints, but this is not usually the case in the peripheral joints. CT is used occasionally to assess extent of disease, as in the orthopedic assessment of large joints when detailed evaluation of bone morphology may be required preoperatively. CT scanning with intra-articular contrast material (CT arthrogram) may be the single most accurate modality for detecting cartilage thinning, fissuring, flaps, or volume⁵⁹ (Figure 58-13), as well as loose intra-articular bodies. This requires both a minimally invasive procedure and radiation exposure and is not widely used.

Figure 58-12 Gout (x-ray and dual-energy computed tomography [CT] scan). X-ray (**A**) and dual-energy CT scans (**B** through **D**) of left hand and wrist of a 39-year-old male patient with recent-onset bilateral pain in hands and wrists. X-ray (**A**) and laboratory investigations were all normal. Dual-energy CT was performed and confirmed the presence of sodium urate crystals in the left wrist and one finger. Left wrist aspirate was attempted but was unsuccessful. The patient responded well to treatment for gout. Imaging findings: After processing of CT data with an algorithm specific for detection of urate crystals (Siemens, Erlangen), the urate crystals are displayed green (arrows) on three-dimensional anterior (**B**), two-dimensional transverse (**C**), and two-dimensional sagittal (**D**) reconstructions.

CT arthrography may be used as a problem-solving tool in patients who are not able to undergo MRI.

Use in Diagnosis, Monitoring, and Prognostication

CT is not currently used in routine clinical practice for the diagnosis of OA; it has no role in monitoring disease because it cannot quantify change in the target tissue (cartilage) without an invasive procedure. Also, no published data on the independent prognostic use of CT are available because good quality radiography usually provides the same or more information.

MAGNETIC RESONANCE IMAGING

KEY POINTS

MRI allows visualization and assessment of peripheral inflammatory and destructive joint and soft tissue involvement in degenerative and inflammatory rheumatic diseases.

MRI is by far the best available method for detecting and monitoring inflammation in the spine and sacroiliac joints in AS and other spondyloarthritides.

MRI allows monitoring of inflammatory soft tissue changes (e.g., synovitis, tenosynovitis, enthesitis) during treatment of patients with peripheral inflammatory joint disease.

Through detection of early inflammatory changes, MRI can contribute to an earlier diagnosis of RA and SpA.

MRI bone edema is uniquely visualized by MRI; this provides prognostic information in RA, SpA, OA, undifferentiated inflammatory arthritis, and possibly other rheumatic arthritides.

The main disadvantages of MRI are its cost and lack of availability.

MRI provides multiplanar tomographic imaging with unprecedented soft tissue contrast, without the use of ionizing radiation, and it allows assessment of all structures

Figure 58-13 X-ray, computed tomography (CT), and CT arthrogram of the knee of in a 46-year-old male patient with unexplained pain and locking. Initial x-rays (**A** and **D**) appear near normal with preserved joint space, a tiny osteophyte arising from the medial tibial spine, and no other definite abnormality. CT scan with sagittal (**B**) and coronal (**E**) reconstructions confirms the presence of osteophytosis (*short arrow*) and a small subchondral cyst (*long arrow*) but show no definite chondral changes. CT arthrogram with sagittal reconstruction (**C**) demonstrates several focal hyaline cartilage thinning (*arrows*) and a meniscal tear. On the coronal reconstruction (**F**), the tibial subchondral cyst is associated with complete loss of overlying hyaline cartilage.

involved in musculoskeletal disease. MRI is more sensitive than clinical examination and x-ray for detection of inflammation and damage in inflammatory and degenerative rheumatologic disorders. Disadvantages of MRI include higher costs and lower availability than radiography, longer examination times, and restriction to a limited anatomic area per session. It should be remembered, however, that costs of MRI represent only a small fraction of the cost of biologic treatment or of the indirect costs of sick leave and early retirement.

After the following section on key technical aspects, characteristics of MRI with respect to diagnosis, monitoring, and prognostication and its clinical utility in RA, SpA, PsA, gout, and OA will be described.

Technical Aspects

MRI is very safe. It involves no ionizing radiation and no increased risk of malignancy, and adverse effects of contrast agents are very rare. However, use of contrast agent should

be avoided in patients with severely impaired renal function because of the risk of nephrogenic systemic fibrosis.

T1-weighted (T1w) imaging sequences are favored by relatively short imaging times, good anatomic detail, and the ability to visualize tissues with high perfusion and permeability, including the inflamed synovium, after intravenous contrast (paramagnetic gadolinium compound [Gd]) injection. Fat and Gd-enhanced tissues have high signal intensity on T1w images (Figure 58-14). T2-weighted (T2w) images depict both fat and fluid/edematous tissues with high signal intensity. They are used together with T1w images in degenerative spine disease, while in inflammatory conditions they are particularly useful when fat saturation (FS) techniques (Figure 58-15), in which the signal from fat is suppressed, are applied. This enhances detection of edematous tissue/fluid located in areas with fatty tissue (e.g., bone marrow edema). FS requires a homogeneous field and high magnetic field strength, which are not available on low-field (<1.0 T) MRI units. The only fat-suppressed sequence possible on low-field MRI, the short tau inversion

Figure 58-14 Rheumatoid arthritis (magnetic resonance imaging [MRI]). Axial T1-weighted precontrast (**A**) and postcontrast (**B**) MRI of the second (left) through fifth (right) fingers at the level of the metacarpophalangeal joints in a patient with rheumatoid arthritis (RA). Synovitis (black arrows in **B**), joint effusion (white arrow in **B**), and severe bone erosion (arrow in **A**) are seen. Coronal T1-weighted precontrast MRI of the wrist (**C**) in another RA patient shows no bone erosions. Similar images 1 year later (**D**) show severe erosive progression (bone erosions marked by arrows).

recovery (STIR) technique, which is based on relaxation time differences, can provide information on bone marrow edema,⁶⁰ but with less detail.

Whereas MRI examination of axial joints requires whole body MRI units, MRI of the peripheral joints can be performed with whole body MRI units or with dedicated extremity MRI units (E-MRI). E-MRI increases the potential for widespread rheumatologic use through markedly lower costs, more comfortable patient positioning, and elimination of claustrophobia.

Some E-MRI units may provide information on synovitis and bone destruction that is not markedly inferior to what is obtained by standard sequences on high-field units,^{60,61} but different machines may perform very differently, and for some units, smaller field of view, longer imaging times, and lack of certain imaging techniques (particularly FS at low field) should be considered.⁶²

Most MRI studies of the sacroiliac joint have used only one imaging plane—semi-coronal (i.e., parallel with the axis of the sacral bone). A supplementary T1w FS sequence may improve the evaluation of erosions,⁶³ and sequences designed for cartilage evaluation (e.g., three-dimensional [3D] gradient echo sequences) may be added.⁶⁴ For maximal sensitivity to changes in the ligamentous portion of the sacroiliac joints, imaging in the semi-axial plane is required.⁶³ This may be recommended when MRI is used for diagnostic purposes, although it is probably not essential when used as an outcome measure in trials. On some indications (e.g., suspected disk herniation), MRI should include axial

images; however, MRI of the spine in SpA generally involves only sagittal images, but these should extend sufficiently laterally to include the frequently involved facet and costovertebral and costotransversal joints.⁶⁵ Bone marrow abnormalities in both sacroiliac joints and spine are detected almost equally well with STIR and contrast-enhanced T1w FS sequences in patients with SpA, so contrast injection generally is not needed.^{66,67} In contrast, injection of contrast increases sensitivity for synovitis in peripheral joints.⁶⁸ For evaluation of structural (sometimes referred to as *chronic*) changes, such as bone erosion, new bone formation, and fat infiltration, T1-weighted images are mandatory. A supplementary T1w FS sequence may improve the evaluation of erosions.⁶³ In peripheral and axial joints, specific sequences designed for optimal cartilage evaluation (e.g., 3D gradient echo sequences) can be applied.⁶⁴

Rheumatoid Arthritis

Most MRI studies in RA have investigated knee, wrist, and finger joints. Although the knee joint is an excellent model joint for methodological studies, the clinical value of MRI is mainly dependent on its power to evaluate wrists, hands, and feet, which is also the primary focus of this section. Reports on other peripheral joints are few and are not essentially different. Definitions of key pathologies in RA and PsA are provided in Table 58-1.

MRI allows assessment of all structures involved in RA (i.e., synovial membrane, intra-articular and extra-articular

Figure 58-15 Rheumatoid arthritis (RA) in clinical remission (magnetic resonance imaging [MRI]) and undifferentiated arthritis (MRI). **A** and **B**, RA patient in clinical remission. Despite clinical remission, coronal short tau inversion recovery (STIR) (**A**) and postcontrast T1-weighted fat-suppressed (**B**) MRI show marked bone marrow edema (osteitis, arrows in **A**) and synovitis (arrows in **B**). **C** through **E**, Patient with undifferentiated arthritis. Axial T1-weighted precontrast (**C**) and postcontrast (**D**) T1-weighted MRI views show synovitis in second and third metacarpophalangeal joints (arrows), whereas the STIR sequence (**E**) shows bone edema (arrow). X-ray was normal. One year later the patient had developed RA, according to the American College of Rheumatology 1987 criteria. (Courtesy Dr. Anne Duer-Jensen, Glostrup, Denmark.)

fluid collections, cartilage, bone, ligaments, tendons, and tendon sheaths) (see Figure 58-14). MRI and histopathologic and miniarthroscopic signs of synovial inflammation are closely correlated.^{69,70} MRI bone marrow edema (see Figure 58-14) represents inflammatory infiltrates in the bone marrow (i.e., osteitis), as has been demonstrated by comparison with histologic samples obtained at surgery in patients with RA.^{71,72} Whereas erosion reflects bone damage that has already occurred, bone marrow edema appears to represent the link between joint inflammation and bone destruction. A high level of agreement for detection of bone erosion in RA wrists and MCP joints (concordance at 77% to 90% of sites) between MRI and CT, the gold standard reference for detection of bony destruction, documents that MRI erosions signify true bone damage.^{48,73}

In the cervical spine, the primary imaging modality is CR, but MRI can provide detailed information on bone

and soft tissue abnormalities, which can serve as a valuable supplement to findings revealed by radiographic evaluation⁷⁴⁻⁸⁰ (see Figure 58-2C). MRI is able to directly visualize pannus tissue (e.g., around the odontoid process). Cord compression on MRI seems a better predictor of deterioration than initial clinical and plain radiographic features, supporting MRI as the imaging method of choice for evaluation of spinal cord involvement in RA.⁸¹

Use in Diagnosis, Monitoring, and Prognostication

Diagnosis. Two recent large follow-up studies of undifferentiated arthritis have documented an independent predictive value of MRI in the diagnosis of RA.^{82,83} The presence of bone edema (see Figure 58-15) had a positive predictive value of 86.1% for subsequent development of RA,⁸² and a prediction model, including clinical hand

Table 58-1 Magnetic Resonance Imaging Definitions of Inflammatory and Structural Lesions in Rheumatoid Arthritis, Psoriatic Arthritis, and Axial Spondyloarthritis

A. Peripheral Joints in RA and PsA¹
Inflammatory Lesions
Synovitis: area in the synovial compartment that shows increased postgadolinium (post-Gd) enhancement* of a thickness greater than the width of the normal synovium
<i>*Enhancement (signal intensity increase) is judged by comparison between T1-weighted (T1w) images obtained before and after intravenous (IV) gadolinium (Gd) contrast.</i>
Tenosynovitis: signal characteristics consistent with increased water content* or abnormal post-Gd enhancement† adjacent to a tendon, in an area with a tendon sheath
<i>*High signal intensity on T2-weighted (T2w) fat-saturated (FS) and short tau inversion recovery (STIR) images, and low signal intensity on T1w images.</i>
<i>†Enhancement is judged by comparison between T1w images obtained before and after IV Gd contrast.</i>
Periarticular inflammation: signal characteristics consistent with increased water content* or abnormal post-Gd enhancement† at extra-articular sites, including the periosteum (“periostitis”) and the entheses (“enthesitis”), but not the tendon sheaths‡
<i>*High signal intensity on T2w FS and STIR images.</i>
<i>†Enhancement is judged by comparison between T1w images obtained before and after IV Gd contrast.</i>
<i>‡Defined as tenosynovitis.</i>
Bone marrow edema: A lesion* within trabecular bone, with signal characteristics consistent with increased water content† and often with ill-defined margins
<i>*May occur alone or surrounding an erosion or other bone abnormalities.</i>
<i>†High signal intensity on T2w FS and STIR images, and low signal intensity on T1w images.</i>
Structural Lesions
Bone erosion: a sharply marginated bone lesion, with typical signal characteristics,* which is visible in two planes with a cortical break seen in at least one plane
<i>*On T1w images: loss of normal low signal intensity of cortical bone and loss of normal high signal intensity of marrow fat.</i>
Bone proliferation: abnormal bone formation in the periarticular region, such as at the entheses (enthesophytes) and across the joint (ankylosis)
B. Axial Disease: Ankylosing Spondylitis and Other Spondyloarthritides²
Inflammatory Lesions
Bone marrow edema: increase in bone marrow signal* on STIR images
Structural Lesions
Bone erosion: full-thickness loss of dark appearance of the cortical bone and change in normally bright appearance of adjacent bone marrow on T1-weighted images†
Fat infiltration: focal increased signal in bone marrow on T1-weighted images‡
Bone spur: bright signal on T1-weighted images extending from the vertebral end plate toward the adjacent vertebra (spine)
Ankylosis: bright signal on T1-weighted images extending across the sacroiliac (SI) joints or extending from one vertebra and being continuous with the adjacent vertebra (spine)
<i>*Reference point for bone marrow signal on STIR images: sacroiliac joints: the center of the sacrum at the same craniocaudal level; spine: the center of the vertebra, if normal. If not normal, the signal in the center of the closest available normal vertebra.</i>
<i>†Reference point for bone marrow signal on T1-weighted images: Sacral bone: the center of the sacrum at the same craniocaudal level; iliac bone: normal iliac marrow at the same craniocaudal level; spine: the center of the vertebra, if normal. If not normal, the signal in the center of the closest available normal vertebra.</i>

¹OMERACT MRI in Inflammatory Arthritis Task Force recommendations for MRI definitions of important pathologies in rheumatoid arthritis and peripheral psoriatic arthritis.^{86,121}

²Canada-Denmark MRI Working Group and MORPHO Group recommendations for MRI definitions of important pathologies in spine and sacroiliac joints in axial spondyloarthritis.^{10,104,105}

From OMERACT MRI in Inflammatory Arthritis Task Force,^{86,121} Canada-Denmark MRI Working Group, and MORPHO Group.^{104,105,107}

arthritis, morning stiffness, positive rheumatoid factor (RF) and MRI, and bone edema score in MTP and wrist joints correctly identified the development of RA or non-RA in 82% of patients.⁸³

According to recent ACR/EULAR 2010 criteria for RA,⁶ classification as definite RA is based on the presence of definitive clinical synovitis (swelling at clinical examination) in one or more joints, absence of an alternative diagnosis that better explains the synovitis, and achievement of a total score of 6 or greater (of a possible 10) from the individual scores in four domains. In the joint involvement domain, which can provide up to 5 points of the 6 needed for an RA diagnosis, MRI and US synovitis count.

In other words, MRI and US can be used to determine joint involvement in the ACR/EULAR 2010 criteria for RA.^{6,84,85}

Monitoring Disease Activity and Structural Damage. To be valuable for monitoring joint inflammation and destruction, a method must be reproducible and sensitive to change. MRI allows quantitative (volume or, for synovitis, early contrast enhancement after intravenous contrast injection) and less detailed (qualitative: presence/absence; semi-quantitative: scoring) evaluation of synovitis, bone edema, and bone erosions. In observational and randomized clinical trials, semi-quantitative scoring by the OMERACT (Outcome Measures in Rheumatology) RA MRI scoring system (RAMRIS) has been used most frequently. It involves

semi-quantitative assessment of synovitis, bone erosions, and bone edema in RA hands and wrists, based on consensus MRI definitions of important joint pathologies and a “core set” of basic MRI sequences.⁸⁶

The OMERACT erosion scores are closely correlated with erosion volumes estimated by MRI and CT. Good intrareader and inter-reader reliability and high sensitivity to change have been reported, demonstrating that the OMERACT RAMRIS system, after proper training and calibration of readers, is suitable for monitoring joint inflammation and destruction in RA.⁸⁷ A EULAR-OMERACT RA MRI reference image atlas has been developed, providing an easy-to-use tool for standardized RAMRIS scoring of MR images for RA activity and damage by comparison with standard reference images.⁸⁸ An MRI joint space narrowing scoring system, which is planned to be used to assess cartilage damage as an adjunct to the RAMRIS system, has recently been developed.⁸⁹

MRI allows more sensitive monitoring of inflammation⁹⁰ and bone erosion (see Figure 58-14)⁹¹⁻⁹³ than clinical and radiographic assessments. A large study of 318 methotrexate-naïve patients demonstrated that inhibition of erosive progression by biologic therapy compared with placebo can be demonstrated on MRI using half the patients and half the follow-up time required for radiography.⁹³

Prognostication. Several studies have demonstrated a predictive value of MRI pathology for radiographic progression in wrist and/or MCP joints. In particular, bone marrow edema (see Figure 58-14) is now established as a strong independent predictor of subsequent radiographic progression in early RA.^{94,95} Regression analyses on 3-year and 5-year follow-up in the two respective cohorts have documented that MRI bone edema is a predictor of long-term radiographic progression.^{96,97}

Small studies have indicated a relationship of baseline MRI findings to long-term functional disability⁹⁸ and tendon rupture at 6 years.⁹⁹

Another issue of high clinical importance is whether MRI is useful in patients in clinical remission (see Figure 58-15), to predict the disease course. MRI and US synovitis is found frequently in patients in clinical remission,^{100,101} and one study reported that baseline US synovial hypertrophy, US power Doppler signal, and MRI synovitis scores in individual joints were significantly related to progressive radiographic damage at 1 year follow-up.¹⁰² This study encourages further exploration of MRI and US for predicting the disease course and for evaluating disease status, including defining remission.

Ankylosing Spondylitis/Axial Spondyloarthritis

MRI allows direct visualization of the abnormalities in peripheral and axial joints and entheses that occur in ankylosing spondylitis (AS), PsA, and other forms of SpA. AS, which is thought to be the most common and most typical form of SpA, is dominated by axial disease manifestations in the spine and sacroiliac joints. In accordance with this, this section will focus mainly on the axial manifestations, and the PsA section that follows will discuss peripheral manifestations.

Because of its ability to detect inflammatory changes in bone and soft tissues, MRI is the most sensitive imaging

modality for recognizing early spine and sacroiliac joint changes in AS.^{26,103} MRI findings indicating active disease in the sacroiliac joints (sacroiliitis) include juxta-articular bone marrow edema and enhancement of the bone marrow and the joint space after contrast medium administration; visible chronic changes include bone erosions, sclerosis, periarticular fatty tissue accumulation, bone spurs, and ankylosis (Figure 58-16). Typical lesions of the spine, which indicate active disease, include spondylitis, spondylodiskitis (Figure 58-17), and arthritis of the facet and costovertebral and costotransverse joints (Figure 58-18).^{26,103,104} Chronic changes, such as bone erosions, focal fat infiltration, bone spurs, and/or ankylosis (see Figure 58-18),¹⁰⁵ frequently occur. Enthesitis is also common and may affect the inter-spinal and supraspinal ligaments and the interosseous ligaments in the retroarticular space of the sacroiliac joints. Some patients also have disease manifestations in peripheral joints and entheses, and these can be visualized by MRI.^{26,103} Definitions of key pathologies in SpA are provided in Table 58-1.

Use in Diagnosis, Monitoring, and Prognostication

Diagnosis. The introduction of MRI has resulted in a major improvement in the evaluation and management of patients with SpA. Diagnosis was previously dependent on the presence of bilateral moderate or unilateral severe radiographic sacroiliitis, as part of the modified New York criteria for AS.²³ This frequently delayed the diagnosis by 7 to 10 years.²⁷ Now, through recent ASAS (Assessment of SpondyloArthritis) classification criteria for axial SpA, MRI serves an integral role, and patients with active sacroiliitis on MRI (Figure 58-19) plus one clinical feature (e.g., psoriasis, enthesitis, uveitis; see reference 28 for a complete list) should be classified as having axial SpA.²⁸ A consensus-based definition of the requirements that constitute active sacroiliitis (i.e., fulfill the MRI portion of the ASAS criteria; “a positive MRI”) has been put forth as bone marrow edema in two or more sites and/or in two or more slices.¹⁰⁶

Recent data demonstrate that incorporating structural damage lesions (erosions) into the criteria would improve the diagnostic utility of MRI.^{107,108} However, in January 2011, ASAS decided to await additional data before considering revision of the definition of a positive MRI in the axial SpA criteria.

Monitoring Disease Activity and Damage. MRI can provide objective evidence of currently active inflammation in patients with SpA (see Figure 58-17).^{26,103} Until the introduction of MRI, disease activity assessment was restricted to patient-reported outcomes, such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and Functional Index (BASFI), because disease activity could not be assessed in a sensitive manner by biochemical (mainly C-reactive protein [CRP]) or physical evaluation.

Several systems have been proposed for assessment of disease activity in the sacroiliac joints and in the spine (see a recent review at reference 109 for details). Reproducible and responsive methods are available.¹¹⁰ Sensitivity to change and the discriminatory ability of the three most frequently used spine scoring systems (the Ankylosing Spondylitis spine Magnetic Resonance Imaging-activity [ASpiMRI-a] score, the Berlin modification of the

Figure 58-16 Sacroiliitis in spondyloarthritis (magnetic resonance imaging [MRI] and x-ray). MRI (**A** through **C**) and x-ray (**D**) of the sacroiliac joints of a 26-year-old male with inflammatory back pain for 4 years. Semi-coronal (**A**) and semi-axial (**B**) short tau inversion recovery images show massive iliac and sacral bone edema around the left sacroiliac joint (i.e., demonstrate severe active sacroiliitis) (long arrows in **A** and **B**). Inflammation (sacroiliitis) is also present in the right sacroiliac joint (short arrow in **A**). T1-weighted semi-coronal image shows fat infiltration (white arrows in **C**) and bone erosion (black arrows in **C**). Anteroposterior radiograph (**D**) shows bilateral mild sclerosis on the iliac side, and bilaterally the articular surface is less well defined than normal, consistent with erosion. However, this feature is exaggerated by overlying bowel gas. (Courtesy Susanne Juhl Pedersen, Glostrup, Denmark.)

ASpiMRI-a score, and the Spondyloarthritis Research Consortium of Canada [SPARCC] scoring system¹¹¹⁻¹¹³) have been demonstrated in clinical trials, and these systems have been tested against each other by the ASAS/OMERACT MRI in AS group.¹¹⁰ All methods were feasible, reliable, sensitive to change, and discriminative. The SPARCC method showed the highest sensitivity to change, as judged by Guyatt's effect size, and the highest reliability, as judged by the inter-reader intraclass correlation coefficient (ICC).¹¹⁰

MRI is much less established for assessment of structural changes (often referred to as *chronic changes*) than inflammatory changes. MRI undoubtedly provides otherwise inaccessible information on inflammatory activity, and just "equality" of MRI with radiography concerning structural damage assessment is a step forward, because radiography and the ensuing need for two examinations and exposure to ionizing radiation could then be avoided. Scoring methods assess erosion, sclerosis, fat deposition, and/or bone bridges separately or by a global score.^{105,111,114} Validation of the methods used for damage assessment is limited, and their value has not yet been clarified.

Prognostication. Three spine studies have documented an association between the presence of bone marrow edema

at the anterior corners of the vertebrae on MRI and subsequent development of syndesmophytes on radiography after 2 years of follow-up. Presence as opposed to absence of MRI anterior inflammation provides relative risks of 3 to 5 for a new anterior radiographic syndesmophyte at that level.¹¹⁵⁻¹¹⁷ In two studies, the association was even more pronounced in those vertebral corners in which inflammation had resolved following institution of anti-tumor necrosis factor (TNF) therapy, possibly explained by TNF in an active inflammatory lesion restricting new bone formation, whereas reduction of TNF achieved by applying a TNF antagonist allows tissue repair to manifest as new bone formation.^{116,117}

One study suggests that with early inflammatory back pain, severe sacroiliac MRI bone marrow edema together with human leukocyte antigen (HLA)-B27 positivity is a strong predictor of future AS, whereas mild or no sacroiliitis, irrespective of HLA-B27 status, is a predictor of not developing AS.¹¹⁸ Data on the value of MRI for predicting therapeutic response in SpA are very limited. A high spine MRI inflammation score and a short disease duration have been reported as statistically significant predictors of clinical response (BASDAI improvement >50%) to anti-TNF therapy.¹¹⁹ Additional and larger studies are needed to

Figure 58-17 Spine inflammation in ankylosing spondylitis (magnetic resonance imaging [MRI]). A 43-year-old man with HLA-B27–positive ankylosing spondylitis with deteriorating symptoms, including inflammatory back pain, had an MRI scan before starting biologic therapy. Baseline sagittal short tau inversion recovery (STIR) MRI (**A**) shows diffuse increased signal (edema) in the T2 vertebral body and multiple foci of corner inflammation anteriorly at T5 and T6, and posteriorly at T7, T8, T9, and T10 (arrows). Other images confirmed extensive active inflammation in the spine. The patient responded very well, and after 6 months of therapy, a repeat STIR MRI (**B**) showed complete resolution of bone marrow inflammation. Subsequently, the patient experienced recurrence of symptoms, and a third MRI (**C**) was performed (2 months after anti-TNF therapy was stopped). This MRI shows no edema at T5-T6, a conspicuous new lesion anteriorly at T7, and recurrent inflammation posteriorly in the lower thoracic spine (arrows).

Figure 58-18 The spine in ankylosing spondylitis (AS) (magnetic resonance imaging [MRI]). **A** through **C**, T1-weighted sagittal MRI of three different patients with AS shows different structural lesions. **A**, Fat infiltration (arrowheads) in the bone marrow of several lumbar vertebral corners and anterior fusion (arrows) at L3-L4 and L4-L5. **B**, Fatty infiltration (arrows) in the bone marrow of multiple vertebral corners in the cervical spine, indicative of the diagnosis of spondyloarthritis. **C**, Extensive increased marrow fat signal (arrows) crossing the costovertebral joints (thoracic ankylosis) is seen, as are changes in several facet joints and other posterior elements. **D**, Sagittal short tau inversion recovery MRI shows intense inflammation in the bone marrow of the transverse processes and facet joints of the lower thoracic spine (arrows), as well as less intense inflammation in several discovertebral joints.

Figure 58-19 Inflammatory back pain (x-ray and magnetic resonance imaging [MRI]). A 31-year-old man with inflammatory back pain. **A**, X-ray of the sacroiliac joints demonstrates only very subtle findings with possible sclerosis on the iliac side of the right sacroiliac joint and subtle spur formation at the inferior margin. **B** and **C**, MRI at the same time shows obvious findings of spondyloarthritis with mild bilateral iliac inflammation on short tau inversion recovery (**B**) and multiple findings on T1-weighted images (**C**), including sclerosis most prominent on the right side and subchondral erosion (arrows), which are very small on the right side and obvious on the left side.

clarify the role of MRI in the prediction of disease course and therapeutic response.

Psoriatic Arthritis

The clinical appearance of PsA is highly diverse and involves the spine, SI joints, peripheral joints, and/or entheses; accordingly, MRI findings vary. PsA shares clinical

manifestations with RA and SpA, and this also applies to its MRI features.¹²⁰ Peripheral PsA synovitis and erosions do not have disease-specific MRI features, and MRI bone edema can involve any bone. General agreement is lacking regarding which joints should be imaged for assessment of PsA activity. This decision may have to be individualized according to the disease pattern observed.

MRI can visualize both peripheral and axial musculoskeletal anatomy and PsA disease manifestations. Findings include synovitis, tenosynovitis, periarticular inflammation, enthesitis, bone edema, bone erosion, and bone proliferation (Figure 58-20).¹²¹⁻¹²⁴ As with other types of SpA, enthesitis, dactylitis, and spondylitis can be seen. Dactylitis has been shown on MRI to be due to tenosynovitis with effusion, sometimes associated with diffuse soft tissue edema and/or synovitis in nearby finger or toe joints (see Figure 58-20).^{125,126} Few MRI studies have examined axial PsA; findings are similar to AS findings but are more frequently asymmetric.^{127,128}

Entheses have attracted attention as a possible primary location of disease.¹²⁹ Nail disease is common in PsA, and distal interphalangeal (DIP) joint inflammation on MRI has been described to extend to the nail bed.¹³⁰

PsA can be clinically silent. In patients with psoriasis without arthritic signs or symptoms, pathologic findings on MRI (including periarticular edema, tendon sheath effusion, intra-articular effusion, synovial pannus, bone erosion, bone cysts, subchondral changes, and joint subluxation) have been reported in more than two-thirds (68% to 92%) versus no to one-twelfth or less of healthy controls.¹³¹⁻¹³³ The clinical importance of these findings has not yet been clarified.

Use in Diagnosis, Monitoring, and Prognostication

Diagnosis. As has been described, MRI can detect the different pathologies involved in PsA. However, no studies have documented that MRI in an early undifferentiated arthritis cohort can be used to differentiate PsA from other arthritides.

Monitoring. Data on monitoring activity and damage are limited. Most studies have reported only qualitative MRI assessments of the different pathologies of PsA.¹²⁰ Quantitative assessment of contrast enhancement has been reported^{134,135} but is insufficiently validated for clinical use. Scoring systems of inflammation and damage have been developed.^{121,136,137} The OMERACT Psoriatic Arthritis Magnetic Resonance Image Scoring System (PsAMRIS)^{121,138} is the best validated and documented, with good intrareader and inter-reader reliability for inflammatory parameters (synovitis, tenosynovitis, and periarticular inflammation) and sensitivity to change. Its usefulness in clinical trials and in practice should be further tested.

Prognostication. No longitudinal studies of the prognostic value of MRI findings in PsA are available.

Gout

MRI can directly visualize the inflammatory (synovitis, tenosynovitis, bone edema, and soft tissue inflammation) and destructive (bone erosion) aspects of gout arthropathy.^{38,139-141} MRI can also visualize tophi and can provide

Figure 58-20 Psoriatic arthritis (magnetic resonance imaging [MRI]). Axial T1-weighted precontrast (**A**) and postcontrast (**B**) MRI of the second (left) through fifth (right) fingers at the level of the fourth proximal interphalangeal joint and sagittal short tau inversion recovery MRI (**C**) of the fourth finger show mild synovitis (long arrows in **B** and **C**) and considerable periarticular inflammation (short arrows in **B** and **C**) around the fourth distal interphalangeal joint and tenosynovitis (arrowheads in **B**). (Courtesy Rene Poggenborg, Glostrup, Denmark.)

information on the inflammatory nature of these lesions, which cannot be appreciated from x-ray or CT. On MRI, tophi typically exhibit low signal on T1w images, with varying postcontrast enhancement and medium-high signal on T2w images, indicating the presence of cellular tissue surrounding or infiltrating the crystalline mass (see Figure 58-6).^{139,141} Calcification within the tophus can lead to regions of low signal on T2w images. Tophi are not always clinically detectable if they are located deep to the skin surface.

Use in Diagnosis, Monitoring, and Prognostication

No study has compared the diagnostic accuracy of MRI-documented synovitis, bone erosion, and/or tophi against gout classification criteria.³⁶ MRI can detect tophi, and the presence of these strongly suggests a diagnosis of gout, but joint aspirate confirmation of monosodium urate crystals is usually required because the differential diagnosis includes infection and other space-occupying lesions.

Monitoring gout by MRI could include assessment of joint inflammation, erosion progression, and extent/size of tophi (see Figure 58-6). Tophus volume assessment by MRI has been reported to have good intrareader and inter-reader reproducibility and may be useful for this purpose in trials.¹⁴² In contrast to RA, AS, and PsA, no MRI scoring system for overall assessment of gouty arthritis has yet been developed.

Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

MRI detects calcification of hyaline cartilage as an area of low signal intensity, especially on gradient echo images; meniscal chondrocalcinosis exhibits increased signal on

T1-weighted and proton density images and may simulate meniscal degeneration or tear (see Figure 58-7).¹⁴³ As in other diseases, MRI is a sensitive method for subchondral cysts and inflammatory changes such as synovitis and effusion.

Septic Arthritis

The MRI appearance of septic arthritis is nonspecific, and similar findings can be observed in other inflammatory arthritides. Thus in case of clinical suspicion of septic arthritis, a joint aspiration must be performed without delay to avoid irreversible articular damage. Characteristic findings include synovitis, joint effusion, and soft tissue edema (see Figure 58-8) followed by bone erosion and cartilage destruction. MRI may be helpful in diagnosing complications of septic arthritis, such as abscesses and osteomyelitis. It should be remembered that most individual findings on MRI are not specific, and bone marrow edema alone does not necessarily denote osteomyelitis.¹⁴⁴ Contrast-enhanced MRI is particularly useful for identifying abscess/necrosis in soft tissue or bone that may confirm the diagnosis and/or requirement for surgical débridement. The painful diabetic foot is a specific clinical presentation for which MRI may now be routinely performed to help distinguish between infection and trauma and to identify nonviable tissues, although scintigraphic studies also play an important role in assessment of these complex patients.⁴²

Osteoarthritis

Based on its tomographic nature and ability to visualize cartilage, bone, and various soft tissues, MRI is very well suited for assessment of inflammatory changes, structural and compositional changes in the cartilage, and

other structural lesions in OA. Most studies have been undertaken in knee joints (Figure 58-21) or, less frequently, in hip joints, but small joints of the hand (see Figure 58-10) have recently been studied in generalized OA.

MRI allows direct assessment of the thickness, surface contour, and internal architecture of articular cartilage in OA¹⁴⁵⁻¹⁴⁷ (see Figure 58-21), making possible the staging and monitoring of OA development. Osteophytes may be seen at the joint margins or beneath the articular cartilage. Subchondral changes include bone edema, sclerosis, and bone cysts. MRI “bone marrow lesions” (sometimes referred

to as bone edema lesions), which are areas with inhomogeneous, intermediate to low signal on T1w and high signal in water-sensitive techniques (STIR/T2FS) (Figure 58-22), have, by comparison with histologic samples obtained by surgery in advanced OA, shown trabecular microfracture and bone marrow fibrosis and/or necrosis but limited interstitial edema.¹⁴⁸⁻¹⁵¹ Synovitis is seen frequently on MRI in patients with OA, albeit to a lesser degree than in those with RA.¹⁵² Synovitis scores obtained by contrast-enhanced MRI have demonstrated a good correlation with arthroscopic and microscopic synovitis scores.¹⁵³

Figure 58-21 Osteoarthritis of the knee (x-ray and magnetic resonance imaging [MRI]). **A**, Anteroposterior x-ray view of the left knee shows large osteophyte of the medial and lateral tibiofemoral joint and mild medial joint space narrowing. **B** and **C**, Coronal proton density-weighted MRI confirms the presence of large osteophytes in the tibiofemoral joint, shows diffuse cartilage loss of the medial tibia and femur, and discloses a denuded bone with complete loss of cartilage in the lateral tibial plateau (arrow in **B**). A small focal cartilage defect of the lateral femoral condyle (arrow in **C**) is also evident. Both lateral and medial menisci are partially macerated, and a subluxation of the medial meniscus is seen, along with severe cartilage loss on the medial and lateral tibial plateau and the medial femoral condyle. **D**, Coronal T2-weighted fat-suppressed MRI shows medial tibial plateau subchondral bone marrow edema (arrow in **D**). (Courtesy Professor Ali Guermazi, Boston, Mass.)

Figure 58-22 Early osteoarthritis (OA) of the knee (x-ray and magnetic resonance imaging [MRI]). X-ray (**A**) and MRI (**B** through **D**) of the knee with early OA. **A**, Anteroposterior x-ray view shows an almost normal knee. The only possible abnormality is a tiny osteophyte at the medial tibial plateau. **B**, Coronal proton density-weighted MRI shows a minimal medial meniscus subluxation (*arrow*). **C**, Sagittal proton density-weighted MRI shows partial maceration of the posterior horn of the medial meniscus (*black arrow*), thinning of the cartilage at the posterior medial tibial plateau (*long white arrow*), and a moderate-sized Baker's cyst (*short white arrow*). **D**, Sagittal fat-suppressed T2-weighted MRI confirms the Baker's cyst (*short arrow*) and also shows subchondral bone marrow edema (*long arrow*) subjacent to the loss of cartilage at the posterior subregion of the medial tibial plateau. (Courtesy Professor Ali Guermazi, Boston, Mass.)

Use in Diagnosis, Monitoring, and Prognostication of OA

Diagnosis. Classification criteria for OA are based on clinical and conventional radiographic findings.⁴⁵ However, the use of MRI in the diagnosis of OA offers the advantages described previously (i.e., that MRI can sensitively depict all involved pathologic changes).

Monitoring. Various quantitative and semi-quantitative techniques have been used to measure structural

abnormalities and change on MRI in patients with OA.¹⁴⁵ Quantitative measurements apply computer-aided image processing to quantitate various aspects (e.g., volumes of cartilage, bone, bone marrow lesions, menisci, or synovium). These have been reported to have excellent reproducibility.¹⁵⁴ Measures of cartilage composition (e.g., quantification of glycosaminoglycan content) are also available.^{146,147} Semi-quantitative methods have been used to perform semi-quantitative “multiple feature” (“whole organ”) assessments in the knee, based on conventional MRI

acquisitions.¹⁵⁵⁻¹⁵⁸ These measures have high reliability and better sensitivity to change than have been noted with x-ray methods.¹⁵⁴

Prognostication. In a recent systematic literature review,¹⁵⁹ quantitative cartilage volume change and the presence of cartilage defects or bone marrow lesions (bone edema) in three of three studies were significantly related to subsequent total knee replacement (i.e., a predictive value was demonstrated).¹⁶⁰⁻¹⁶²

Furthermore, enlargements in bone marrow lesions (BMLs) have been demonstrated to be related to increased pain (and improvements in bone marrow lesions to decreased pain) in follow-up studies.^{163,164} In contrast, inconsistent and generally weak relations between cartilage loss and symptom change and a weak relation between change in synovitis and change in pain have been reported. Finally, the presence of meniscal damage, cartilage defects, and/or BMLs predicts subsequent MRI progression.¹⁵⁹

ULTRASONOGRAPHY

KEY POINTS

US allows sensitive visualization and assessment of peripheral inflammatory and destructive joint and soft tissue involvement in a variety of degenerative and inflammatory rheumatic diseases.

US can be performed easily by trained rheumatologists in relation to the clinical examination.

US can, through detection of early inflammatory changes, contribute to earlier diagnosis of RA.

Grayscale and/or power Doppler US allows monitoring of soft tissue changes (e.g., synovitis, tenosynovitis, enthesitis) during treatment of patients with peripheral inflammatory joint disease.

US allows guidance of invasive procedures, making possible precise needle positioning for aspirations and injections (e.g., in joints, bursae, or tendon sheaths or at entheses).

The main disadvantages of US include the need for the presence of a skilled investigator, the inter-reader and interscanner variability, and the need for an “acoustic window.”

Ultrasonography (US) is an evolving imaging technique that is used increasingly by rheumatologists in daily clinical practice. This trend has been confirmed over the past few years by extensive publications and a wide body of literature.^{165,166} In some countries, including Belgium, Italy, Germany, and Spain, US has become an integral part of rheumatology training. Absence of radiation, good visualization of the joint cavity, low running costs, multiplanar imaging capability, quantification of soft tissue abnormalities, and real-time assessment are the main advantages of US over other imaging techniques. Moreover, US is rapidly performed, is readily accepted by patients, and is used increasingly for guidance during invasive procedures (e.g., biopsy, joint aspiration, injection).¹⁶⁷

US provides a clear view of the anatomic damage induced by inflammatory or degenerative conditions; it allows an

accurate assessment of joint and soft tissue involvement in a variety of rheumatic diseases, including RA, AS, and other spondyloarthritides, as well as crystal deposition diseases, septic arthritis, systemic lupus erythematosus (SLE), systemic sclerosis, polymyositis, Sjögren's syndrome, vasculitis, osteoarthritis, and regional pain syndromes (Figure 58-23).

US is very useful as a source of guidance for invasive procedures.^{167,168} US-guided needle placement within the selected target area is an accurate and safe approach in the treatment of patients requiring aspiration of synovial fluid, injection therapy, or biopsy. Under US guidance, progression of the needle in the soft tissue toward the selected target area can be carefully controlled, thereby avoiding injury induced by the tip of the needle and/or complications such as subcutaneous or intratendinous injection of corticosteroid, which introduces a high risk of tissue damage. Moreover, US-guided injections for inflammatory arthritis are significantly less painful than palpation-guided models, and even though recent studies have not been able to demonstrate significantly improved clinical outcomes,^{169,170} US guidance may improve clinical outcomes and enhance cost-effectiveness.

US can be used in daily rheumatology practice for a wide spectrum of indications (see “Key Points: Ultrasonography”).

Technical Aspects

Musculoskeletal US requires high-quality equipment. Low-frequency transducers (3.5 to 5 MHz) are useful for exploring deep targets (e.g., hip, sacroiliac joints). Medium-frequency transducers (6 to 13 MHz) represent the best choice for exploring large joints (e.g., shoulder, knee, elbow). High-frequency transducers (14 to 22 MHz) have a low penetration power of the ultrasonic beam but provide an accurate assessment of superficial structures (e.g., tendons, finger joints), reaching a resolution power of less than 0.1 mm.

US is an operator-dependent technique. Thus, the quality of the pictures and the interpretation of sonographic images depend on the quality of the US equipment, the technical conditions of the examination, and the skills and experience of the examiner.

Color Doppler and power Doppler US explore blood perfusion and may play a key role in monitoring inflammatory disease activity and in assessing response to therapy.¹⁷¹ Color Doppler provides information on the direction of blood flow. Power Doppler has greater sensitivity in detecting blood flow but is not able to determine flow direction or velocity. Use of US contrast agent enhances the detection of tissue vascularity with Doppler US, and this may have an impact on the detection of subclinical synovitis.¹⁷² However, the use of ultrasound contrast agents for assessment of rheumatic diseases remains restricted to the research field in terms of ethical and cost/efficacy reasons.

US is a continuously evolving technique; recent advances in technology promise additional improvements, especially in the fields of three-dimensional (3D) and four-dimensional (4D) US, elastosonography, and fusion imaging.¹⁷³ Three-dimensional US has the potential to dramatically reduce the duration of the US examination and to improve

Figure 58-23 Various regional pain syndromes (ultrasonography). **A**, Shoulder (anterior transverse scan): fluid collection in the subdeltoid bursa (asterisk). **B**, Achilles tendon (at) (longitudinal scan): large tendon tear (arrow). **C**, Knee (posterior longitudinal scan): massive fluid collection inside the semi-membranosus gastrocnemius bursa (popliteal cyst) (asterisk). **D**, Elbow: epicondylitis characterized by intense power Doppler signal within the common extensor tendon of the fingers (tec). bt, long head of the biceps tendon; c, calcaneus; d, deltoid muscle; g, gastrocnemius muscle; o, lateral epicondyle; r, radial capitellum.

standardization of the technique. Longitudinal, transverse, and coronal planes and three-dimensional reconstruction of the target area can be completed in a few seconds.¹⁷³

Elastosonography is a new technique for assessing tissue elasticity. Its main potential application in rheumatology includes skin assessment in systemic sclerosis, evaluation of tendon stiffness, and differential diagnosis of subcutaneous nodules.

Fusion imaging allows simultaneous comparison and mapping of US images onto another preacquired imaging modality such as CT or MRI.

Examination Technique

US examination of the musculoskeletal system should be performed with multiplanar scans. European League Against Rheumatism (EULAR) guidelines have been produced to standardize the approach to musculoskeletal US in rheumatology.¹⁷⁴

Patient position is critical in performing a US examination correctly. Particular attention must be paid to the angle of the US beam, which must be perpendicular to the examined structure to avoid anisotropy-dependent artifacts (spatial asymmetry). These artifacts may generate diagnostic errors, especially when fibrillar or fascicular structures such as tendons and nerves are studied. Both longitudinal and transverse scans should be performed by slightly moving the transducer from radial to ulnar and from proximal to distal sides to enable maximum coverage of the anatomic surface area.

Operator dependency is the main shortcoming of US. Adequate supervised training is essential to ensure the

correct use of US and appropriate interpretation of results. Another limitation of US is seen in the comprehensive assessment of some anatomic areas (spine, sacroiliac joint, and hip) caused by lack of adequate “acoustic windows.” Pitfalls and errors most often are related to misinterpretation of normal anatomy, inadequate regulation of the US beam, and inappropriate examination technique, mainly depending on pressure, position, and inclination of the probe.

US findings provide a wide range of useful information concerning the main tissue changes that occur in patients with rheumatic disease. However, standardization about scanning methods and definitions of basic sonographic abnormalities remain limited. The most widely accepted definitions for sonographic pathology were published in 2005 by the OMERACT special interest group (Table 58-2).¹⁷⁵

Rheumatoid Arthritis

RA is the inflammatory condition most frequently studied by US. US abnormalities detected in patients with RA include joint space widening, fluid collection, synovial hypertrophy, cartilage defects, bone erosions, tendon sheath widening, and tendon tears.¹⁷⁶ Joint cavity widening is the earliest characteristic US finding of synovitis. Even minimal intra-articular fluid collection and synovial proliferation may be revealed by US. Fluid collection shows a typical anechoic pattern that can easily be distinguished from the soft echogenicity of synovial hypertrophy. This appears as a homogeneous thickening of the synovial layer or as irregularly shaped clusters of echoes (bushy and villous

Table 58-2 Definitions of Ultrasonographic Pathology in Inflammatory Joint Disease

Bone erosion: an intra-articular discontinuity of the bone surface that is visible in two perpendicular planes
Synovial fluid: abnormal hypoechoic or anechoic (relative to subdermal fat, but sometimes may be isoechoic or hyperechoic) intra-articular material that is displaceable and compressible but does not exhibit Doppler signal
Synovial hypertrophy: abnormal hypoechoic (relative to subdermal fat, but sometimes may be isoechoic or hyperechoic) intra-articular tissue that is nondisplaceable and poorly compressible and that may exhibit Doppler signal
Tenosynovitis: hypoechoic or anechoic thickened tissue with or without fluid within the tendon sheath, which is seen in two perpendicular planes and may exhibit Doppler signal
Enthesopathy: abnormally hypoechoic (loss of normal fibrillar architecture) and/or thickened tendon or ligament at its bony attachment (may occasionally contain hyperechoic foci consistent with calcification), seen in two perpendicular planes that may exhibit Doppler signal and/or bony changes, including enthesophytes, erosions, or irregularity

From OMERACT Ultrasonography Task Force.¹⁷⁵

appearance). Doppler signal may be particularly intense inside areas of synovial hypertrophy in patients with active synovitis. Assessment of perfusion of synovial tissue may prove to be the most important part of evaluating RA joints in that differentiation between inactive and persistent inflammation in the rheumatoid joint is one of the most important tasks for the clinician because it may have a great impact on clinical decision making.

Detection of a highly perfused synovial pannus in patients with early arthritis should be regarded as a potential predictor of the future appearance of anatomic damage (Figure 58-24). US can also be used in assessing cartilage damage at metacarpophalangeal joint level in patients with RA (Figure 58-25).

The high spatial resolution of US allows recognition of even minimal bone erosion. Sensitivity is highest in easily US-accessible areas, including the frequently involved second metacarpophalangeal and fifth metatarsophalangeal joints.^{48,177,178} Bone erosions are viewed on US as an interruption of the sharp hyperechoic bone profile. US depicts the wall and the floor of the erosions that in most cases are filled by a hyperperfused synovial pannus. It has been demonstrated that US can be used to detect more erosions than x-ray, especially in early RA, and that US erosions are true erosions when compared with CT used as the gold standard.^{48,49,179}

Tendon involvement is frequent and characteristic in patients with RA. The spectrum of pathologic changes detectable in tendons by US is wide and heterogeneous. Tendon sheath widening, loss of the normal fibrillar echotexture, and loss of definition of tendon margins in partial or total tears are the abnormalities that characterize tenosynovitis.¹⁷⁶ Circumscribed or extensive collection of anechoic fluid within the synovial sheath is the most characteristic feature of exudative tenosynovitis. The presence of echoes within the tendon sheath can be related to synovial proliferation and/or to aggregates of cells and proteins.

Figure 58-24 Rheumatoid arthritis (ultrasonography). **A**, Metacarpophalangeal joint (dorsal longitudinal scan): joint cavity widening, synovial hypertrophy (sh), and intense power Doppler signal. **B**, Fifth metatarsophalangeal joint (lateral longitudinal scan): large bone erosion (arrows) associated with power Doppler signal inside the erosion. **C**, Tibialis posterior tendon (tp): tendon sheath widening with homogeneous anechoic aspect of the content (fluid collection) (asterisk). **D**, First compartment of the finger extensor tendons (longitudinal scan): chronic tenosynovitis characterized by synovial hypertrophy and intense power Doppler signal. a, astragalus; at, abductor pollicis longus tendon; et, common extensor tendon of the finger; m, metacarpal bone; mh, metatarsal head; mm, medial malleolus; pp, proximal phalanx.

Figure 58-25 Cartilage in rheumatoid arthritis (ultrasonography). Hyaline cartilage (circle) of the metacarpal head (m) in healthy subject (A) and in patients with early (B) and advanced (C and D) rheumatoid arthritis. Loss of cartilage is homogeneous in different stages of the disease. Early (B), late (C), very late (D).

Very subtle changes in tendon structure can be detected in patients with early RA. Their predictive value in detecting more aggressive or rapidly progressive forms of disease has not been clearly defined, and follow-up investigations are needed. Early circumscribed tendon tears appear as minimal fragmentation of small groups of contiguous fibrils; this represents a characteristic loss of the normal fibrillar echotexture of the tendon. In more advanced stages of structural damage, tendons can be subjected to large partial tears or to complete rupture. If the US beam and the major axis of the tendon are not perfectly perpendicular, certain areas of the tendon appear anechoic (anisotropy artifacts) and thus may be mistakenly interpreted as possible tendon ruptures.

US is sensitive for the detection of arthritis when several joints are examined. A significantly higher number of inflamed joints are found by US than by clinical assessment. However, US examination of 78 joints requires 70 minutes, and examination of even a seven-joint set can be challenging in daily clinical practice.^{180,181}

Use in Diagnosis, Monitoring, and Prognostication of RA

Diagnosis. The ability of US to allow visualization of intra-articular and extra-articular changes suggests that it can be used to assist clinicians in reaching a specific diagnosis (e.g., in patients with early undifferentiated arthritis). However, data describing the differential diagnostic value of US in patients with undifferentiated arthritis are very limited. In the seronegative (RF and anticitrullinated protein antibody (ACPA) negative) subgroup of 50 early undifferentiated inflammatory arthritis patients, certain clinical and radiographic features (elevated CRP, swollen joints, and radiographic erosion) raise the

probability of persistent inflammatory arthritis from 6% to 30%, whereas the addition of one to three specific US features (grade 3 grayscale synovial hypertrophy, at least grade 2 synovial power Doppler signal, and at least one erosion) increased the probability to 50% to 94%, suggesting that combining ultrasonographic evaluation with routine assessment in seronegative early arthritis may markedly increase the certainty of diagnosis.¹⁸² In seropositive disease (RF and/or ACPA positive), US had no predictive value.

Monitoring Disease Activity and Damage. Even though international consensus has not yet been reached on the best possible scoring system and joints to score in the assessment of synovitis and other joint pathologies in RA,^{181,183} the OMERACT Ultrasonography Task Force has developed definitions for various joint pathologies that can be used for further development and validation. US measures that correlate with synovitis (Doppler signal and B-mode synovial membrane thickness) decrease in parallel with other markers of disease activity when glucocorticoids^{171,172,184-186} or TNF antagonists¹⁸⁷⁻¹⁹² are administered, indicating their potential for monitoring joint inflammation in RA.¹⁹³ US allows visualization of cartilage changes and bone erosion in accessible areas,¹⁹⁴⁻¹⁹⁷ but data are lacking on its reproducibility and sensitivity to change.

Thus, US is probably a valid method for monitoring synovitis and, in accessible areas, damage progression, but the relative advantage of US over x-ray for showing damage progression remains unclear, and more data are needed on reproducibility (e.g., probe positioning, selection of site for the picture, machine selection, machine/pressure adjustments) and sensitivity to change when the entire US examination is repeated.

Prognostication. Data on the predictive value of US findings are ambiguous. One study found US synovitis to be predictive of future radiographic progression in patients

treated with conventional DMARDs but not with anti-TNFs¹⁹⁰; another found no significant correlation between baseline clinical, laboratory, functional, and US parameters and 1-year follow-up DAS28 (measure of disease activity in RA), Health Assessment Questionnaire (HAQ) score, and radiographic scores in DMARD-treated patients.¹⁹⁸

The Leeds group has reported that US (and MRI) evidence of joint inflammation are frequent in patients in clinical remission.^{102,199-202} Baseline US synovial hypertrophy, US power Doppler, and MRI synovitis scores in individual joints were significantly related to progressive radiographic damage. Furthermore, a significant association was noted between power Doppler score at baseline and structural progression over 12 months in asymptomatic MCP joints and 12 times higher odds of structural progression in joints with increased power Doppler signal.^{100,202} In a recent study of the same group of RA patients in clinical remission on anti-TNF, US could not predict who could successfully stop anti-TNF therapy.²⁰¹ It remains to be determined whether US can predict long-term disease

progression, structural damage progression, and preservation of function better than traditional clinical or serologic scores.

Ankylosing Spondylitis/Axial Spondyloarthritis

Despite the fact that contrast-enhanced Doppler US has been reported to have a high negative predictive value for the detection of sacroiliitis,²⁰³ the role of US in assessment of sacroiliac and spine involvement in AS and other types of axial SpA is minimal.

AS and other types of axial SpA frequently involve peripheral joints and entheses. US of peripheral involvement in SpA is described in the following section on PsA.

Psoriatic Arthritis

US assessment of patients with PsA should be focused on joints, tendons with and without a synovial sheath, entheses, skin, and nails (Figure 58-26).²⁰⁴ Basic sonographic

Figure 58-26 Psoriatic arthritis (ultrasonography). **A**, Wrist (dorsal longitudinal scan): marked joint cavity widening of both radiocarpal and intercarpal joints with intense power Doppler signal. **B**, Proximal interphalangeal joint (longitudinal volar scan): chronic tenosynovitis with areas of low tendon echogenicity (arrowheads) and power Doppler signal. **C**, Metacarpophalangeal joint (dorsal longitudinal scan): peritendinous inflammation characterized by hypoechoic swelling surrounding the extensor digitorum tendon (asterisk) associated with power Doppler signal and subcutaneous edema (circle). **D**, Distal patellar enthesis (longitudinal anterior scan): thickening of the enthesis associated with intense power Doppler signal and bone erosion (arrowhead). **E**, Psoriatic plaque: hypoechoic subepidermal thickening (circle) with intense power Doppler signal (asterisk) indicating vasodilatation and angiogenesis. **F**, Psoriatic onychopathy: loss of the normal trilaminar aspect of the nail plate (arrow), thickening of the nail bed (asterisk), and intense power Doppler signal. c, capitate; cet, common extensor digitorum tendons; dp, distal phalanx; et, common extensor tendon of the finger; ft, flexor finger tendons; l, lunate; m, metacarpal bone; mp, middle phalanx; pa, patella; pp, proximal phalanx; pt, patellar tendon; r, radius.

changes in joint and synovial tendons can be similar to those of RA. However, a highly hypervascularized pannus seems to be more prominent in PsA patients in both small and large joints. This feature appears to be related to histopathologic findings.²⁰⁵ Tendons without synovial sheaths are characteristically involved in PsA. Inflammatory changes detectable by US include loss of fibrillar echotexture and focal or diffuse hypoechoic tendon thickening due to intra-tendinous edema, with or without power Doppler signal. Moreover, peritendinous inflammation may appear as a hypoechoic swelling of soft tissue surrounding the tendon, which may show power Doppler signal.²⁰⁶

US can detect a wide range of abnormalities of the enthesis. They consist of enthesal thickening, focal hypoechoic, loss of the homogeneous fibrillar echotexture, irregularity of the bone profile (enthesophytes and/or bone erosions), and power Doppler signal. Evidence supports the use of US as a very sensitive tool for detecting subclinical enthesopathy in patients with psoriasis who have no clinical signs of arthritis and/or enthesitis. Hyperechoic thickening of the epidermis with or without acoustic shadowing and hypoechoic swelling of the dermis with evident power Doppler signal are the main US features of psoriatic plaque.

Both the nail plate and the nail bed can be accurately depicted by US, and a wide range of abnormalities can be detectable, including thickening and loss of the typical trilaminar aspect of the nail plate with or without increased Doppler signal at the nail bed.²⁰⁴

Use in Diagnosis, Monitoring, and Prognostication of PsA

Diagnosis. US is more sensitive than clinical examination for detection of synovitis, tenosynovitis, and enthesitis in patients with PsA,²⁰⁷⁻²⁰⁹ but no studies have yet documented that US in an early undifferentiated arthritis cohort can be used to differentiate PsA from other arthritides. Because enthesitis is prominent in patients with SpA and may precede joint symptoms, it has been of interest to evaluate entheses by using US as a means of diagnosing SpA and therefore also PsA.²¹⁰ A recent study indicates that early US enthesitis will predict the development of SpA.²¹¹ Further work is needed to clarify the role of US in the diagnosis of PsA.

Monitoring. Most studies that aim to monitor treatment response have applied semi-quantitative scoring systems for grayscale and/or Doppler changes.^{212,213} TNF blocker treatments have provided significant reductions in grayscale and Doppler semi-quantitative synovitis scores,²¹² in enthesal morphologic abnormalities, in power Doppler signal, and in bursitis.²¹⁴ Several systems for assessment of enthesitis have been proposed.²¹⁵⁻²¹⁷ No system has been sufficiently validated to be used for monitoring PsA or other spondyloarthritis. More research is needed before standardized, reliable, and responsive US outcome measures in PsA are available.

Prognostication. No studies have evaluated the role of US in prognosticating PsA. Enthesal involvement in patients with psoriasis but without clinical PsA indicates that enthesitis may be a predictor of development of PsA.²¹⁸ However, longitudinal studies are required to clarify this.

Gout

US can detect monosodium urate crystal deposition on the cartilage surface, inside the joint cavity, and around and inside the tendons. The spectrum of the US appearance of urate crystal aggregates can vary from homogeneously punctate to sharply defined hyperechoic densities of variable size and eventually to dense tophaceous material with posterior acoustic shadows.²¹⁹ Joint cavity widening is the most frequent US finding in patients with acute gout.

Monosodium urate crystal deposition on the surface of the articular cartilage results in hyperechoic enhancement of the chondrosynovial margin, which can range from homogeneous thickening of the chondrosynovial interface to areas of focal deposition.²²⁰ Bone erosions are frequently detectable in patients with chronic gout.

Asymptomatic and symptomatic involvement of tendons is common in patients with gout. Urate crystal aggregates of variable size and shape are frequently detectable, especially at the patella and the Achilles tendons. The normal fibrillar echotexture of tendons can be completely altered by the presence of intratendinous monosodium urate deposits, which appear as areas of inhomogeneous echogenicity, sometime generating an acoustic shadow (Figure 58-27).²²⁰

Use in Diagnosis, Monitoring, and Prognostication

The detection of tophi could be helpful in diagnosing gout, especially when these lesions are not detectable clinically. However, although detection of a nodule with a characteristic appearance on US, MRI, or CT is highly suggestive of gout, joint aspirate confirmation of monosodium urate crystals is usually required to rule out infection or other space-occupying lesions. Tophus size can be reliably assessed by US, and this may be useful for monitoring treatment efficacy in clinical trials.^{142,219} No US scoring system has been developed for overall assessment of gout. The prognostic value of US findings is not known.

Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

US has been found to be highly sensitive in detecting aggregates of calcium pyrophosphate dihydrate (CPPD) crystals.^{220,221} CPPD aggregates range from tiny circumscribed hyperechoic spots to extended deposits with or without acoustic shadow. As indicated by EULAR recommendations for calcium pyrophosphate deposition: "US can demonstrate CPPD in peripheral joints, appearing typically as thin hyperechoic bands within hyaline cartilage and hyperechoic sparkling spots in fibrocartilage. Sensitivity and specificity appear excellent and possibly better than those of conventional x-rays."²²² Moreover, floating aggregates of crystals can be observed inside fluid collections (see Figure 58-27).

Septic Arthritis

Septic arthritis is a major emergency in rheumatology. The role of US is to provide early findings that can raise the suspicion of joint infection. Synovial fluid in septic arthritis may show a variable degree of reflectivity. The effusion can

Figure 58-27 Gout and calcium pyrophosphate dihydrate (CPPD) crystal deposition disease (ultrasonography). **A** through **C**, Gout. **A**, Chronic gout. Metacarpophalangeal joint (longitudinal scan with fingers in full flexion): hyperechoic enhancement of the chondrosynovial interface (*arrow*) due to monosodium urate crystal deposition. **B**, Distal patellar enthesis (longitudinal anterior scan): intratendinous monosodium urate deposits (*arrows*). **C**, Distal patellar enthesis (longitudinal anterior scan): tophaceous deposits (*arrow*) surrounded by power Doppler signal. **D** through **F**, CPPD crystal deposition disease. **D**, Achilles tendon (at) (longitudinal scan): intratendinous linear hyperechoic deposits without acoustic shadow (*arrow*). **E**, Femoral hyaline cartilage (transverse scan): calcium pyrophosphate deposits within the hyaline cartilage (*arrows*). **F**, Knee (longitudinal lateral scan): diffuse meniscal calcification (*arrows*). c, calcaneus; f, femur; fc, femoral condyle; m, metacarpal head; pa, patella; pp, proximal phalanx; pt, patellar tendon; ti, tibia.

range from hyperechoic to hypoechoic with a diffuse pattern of low-level echoes. Power Doppler signal is generally intense most often in periarticular soft tissues. Sonographically guided aspiration of even minimal collections of synovial fluid may play a key role in the early differential diagnosis of acute monoarthritis. Bone and cartilage damage may be detectable in a few days if aggressive treatment is delayed.

Osteoarthritis

US is exquisitely sensitive in detecting structural changes in the articular cartilage.²²³ Irregularity and/or loss of the thin and sharp contour of the outer border of the hyaline cartilage and/or increased cartilage echogenicity with patchy or diffuse loss of clarity is the earliest US feature of OA. These changes seem to reflect structural alterations such as fibrillation of cartilage and cleft formation. Variable loss of cartilage is detectable in patients with more advanced disease. Alteration of subchondral bone ranging from tiny

irregularity of the bone profile to multiple erosions can be detected in areas that appear normal on conventional x-ray in both erosive and nonerosive OA. A slight increase in cartilage thickness caused by inflammatory edema in the early phases of OA has been described.

Osteophytes are the most frequent and characteristic abnormalities of the bone profile in patients with OA. They appear as irregularities of the bone contour with posterior acoustic shadow. Joint effusions are commonly found in patients with OA. Minimal fluid collections that are not detectable on clinical examination are easily demonstrated by US. The inhomogeneous echogenicity of synovial fluid can be related to proteinaceous material, cartilage fragments, aggregates of crystals, and calcified loose bodies. Popliteal cysts are frequent in patients with knee OA. US provides structural details about the content of the cyst, its communication with the joint space, and possible compression of adjacent vascular structures. Cyst size and shape vary widely, ranging from small (<1 cm) to giant multiloculated formations. Synovial hypertrophy in OA may show

sonographic features similar to those observed in patients with RA but without the invasive properties of the rheumatoid synovitis.

US-detected synovial inflammation and effusion are common in painful knee OA and correlate significantly with knee synovitis, effusion, and clinical parameters suggestive of an inflammatory “flare.” As in RA, US detects more joints with inflammation than can be detected by clinical assessment.

Diagnosis, Monitoring, and Prognostication

Diagnosis. Classification criteria for OA are based on clinical and conventional radiographic findings, not on US.⁴⁵ However, the use of US in the diagnosis of OA is favored by the fact that US can visualize the pathologic changes previously described.

Monitoring. US can demonstrate changes in synovitis thickness, effusion size, and popliteal cyst size.²²⁴ With respect to structural changes, including cartilage damage, the sensitivity to change remains to be determined. Reproducibility data are scarce, and no consensus on scoring systems has been reached. Quantitative assessment of cartilage is restricted to thickness because total volumes cannot be measured. More work is required to develop standardized definitions of pathology and to demonstrate the validity of US in OA.²²⁵

Prognostication. The significance of ultrasonographically detected pathologic conditions in OA with regard to symptoms, prognosis, outcome, and response to therapy remains to be determined.²²⁶

OTHER IMAGING MODALITIES

Digital X-Ray Radiogrammetry (DXR)

KEY POINTS

DXR performs automated assessment of conventional hand x-rays and provides an approximated bone mineral density (BMD).

Bone loss as measured by DXR-BMD may be useful for monitoring and predicting bone damage in RA.

Three types of bone loss are early features of RA: focal articular bone erosion, periarticular osteopenia, and systemic osteoporosis. Periarticular bone loss is frequently the earliest radiographic feature of RA, is associated with disease activity, and is known to precede bone erosions.²²⁷ However, radiographic osteopenia is detected only when bone loss is greater than 30%.²²⁸

Digital x-ray radiogrammetry (DXR) is a fully automated technique used to perform radiogrammetry from standard hand radiographs to bridge the gap between radiogrammetry and bone densitometry. DXR technology is based on combined computerized radiogrammetric and textural analyses of the narrowest parts of the second, third, and fourth metacarpal bones. Based on cortical thickness (cm), porosity index, and an assumption of a constant bone density and elliptical bone, DXR calculates an approximated bone mineral density (BMD; g/cm²).²²⁹ Short-term precision of

DXR-BMD (coefficient of variation [CV]) and long-term precision have been reported as 0.28% and 0.25%, respectively, and reproducibility as 0.05% to 0.27%.^{230,231}

DXR is highly correlated with periarticular BMD measurements and therefore can reflect periarticular bone loss, even though it measures midshaft cortical bone.²³² DXR-BMD shows greater loss in RA patients with high levels of inflammation, positive rheumatoid factor, or positive ACPA. Further, measurements of DXR-BMD changes are significantly associated with progression of structural damage in early RA subjects.²³³ Losses seen over 1 year with DXR-BMD are predictive of subsequent erosive development.²³⁰ However, so far only changes in DXR-BMD have been shown to be of predictive value, limiting its clinical applicability. DXR-BMD changes have also been shown to be responsive to treatment interventions. During disease-modifying treatment, DXR-BMD losses are less severe in patients responding to treatment than in those who are not responding.^{230,232,233} This suggests that DXR-BMD can become a useful outcome measure and predictor of joint damage in RA clinical trials. However, its clinical usefulness and applicability have yet to be established.

Capillaroscopy

KEY POINTS

Capillaroscopy allows “in vivo” assessment of the microcirculation.

A wide spectrum of abnormalities, including architectural disorganization, enlarged loops, and avascular areas, can be detected in patients with systemic sclerosis and related conditions.

Capillary loss and avascular areas may be related to more extensive skin and/or visceral involvement and a poor prognosis.

Capillaroscopy has proved to be a valuable technique for “in vivo” assessment of microcirculation. Distinctive nailfold capillary abnormalities have been described in a wide spectrum of conditions, including systemic sclerosis, mixed connective tissue disease, dermatomyositis, Sjögren’s syndrome, vinyl chloride disease, Raynaud’s phenomenon, vibrating tools disease, and acrocyanosis.²³⁴

Capillaroscopy can be performed using various optical instruments such as ophthalmoscope, stereomicroscope, photomacrography system, and videomicroscopy equipment.²³⁵ In vivo assessment of skin capillaries is generally performed at the nailfold, where the major axis of the capillaries is parallel to the skin surface. The general configuration of the cutaneous capillaries at the nailfold is “hairpin-like” or “U-shaped.”²³⁴ However, a wide range of variability has been noted among healthy subjects and between the fingers of the same individual. The best visibility of the nailfold capillaries is generally found at the fourth and fifth fingers of the nondominant hand.

The main capillaroscopic parameters to be evaluated include skin transparency, visibility of the subpapillary venular plexus, architectural structure of the microvascular network, density and spatial distribution of capillaries,

Figure 58-28 Nailfold capillary microscopy. **A**, Healthy subject. **B**, Scleroderma pattern: hemosiderin deposits due to previous capillary leakage and marked nonhomogeneity in shape, size, and distribution of capillaries. **C**, Scleroderma pattern: architectural disorganization and irregularly enlarged loops. **D**, Scleroderma pattern: avascular area surrounded by irregular angiogenesis and a giant loop.

morphologic characteristics of the loops, diameters of afferent and efferent limbs, and blood flow characteristics.

A wide spectrum of nailfold capillary changes can be detected in more than 95% of patients with systemic sclerosis. The most characteristic abnormalities include architectural disorganization, irregularly enlarged loops, bushy capillaries, loss of capillaries, and avascular areas. Such capillary abnormalities can be recognized, even in the early stages of systemic sclerosis, when the clinical features are limited to those of Raynaud's phenomenon (Figure 58-28).²³⁶

Capillary loss and avascular areas have been associated with more extensive skin and/or visceral involvement and a poor prognosis. Even if progression of capillary loss is thought to be related to disease duration, avascular areas can represent the first dramatic capillaroscopic finding in recent-onset systemic sclerosis, especially in men with aggressive disease.

Growing interest has been expressed in the use of capillaroscopy to assess the efficacy of treatment in patients with systemic sclerosis. Reduced capillary loss was observed after treatment with cyclosporin A and intravenous iloprost.

In patients with clinically isolated Raynaud's phenomenon, even circumscribed abnormalities such as megacapillaries and irregularly enlarged loops should alert the physician to the possibility of an underlying scleroderma spectrum disorder.

Capillaroscopic changes in patients with undifferentiated connective tissue disease and dermatomyositis may be quite similar to those seen in patients with systemic sclerosis. However, relevant features of angiogenesis can be the dominant capillaroscopic abnormality in dermatomyositis. A scleroderma-like pattern can also be detectable in primary

Sjögren's syndrome, especially when associated with Raynaud's phenomenon.

Tortuosity, loop elongation, enlarged and/or branching loops, and improved visibility of the subpapillary venous plexus have been reported in about 50% of patients with systemic lupus erythematosus. Even if these abnormalities appear to be nonspecific, some of them, especially enlarged loops and capillary loss, have been correlated with lung involvement. Morphea and eosinophilic fasciitis are usually characterized by a capillaroscopic pattern within the normal range.

Nuclear Medicine

KEY POINTS

Nuclear imaging provides not only morphologic but also physiologic information regarding the metabolic state of tissues.

Positron emission tomography (PET) can be useful in the diagnosis and management of vasculitis fever of unknown origin, and malignancies.

Other imaging modalities are generally better suited than nuclear medicine for investigating inflammatory and degenerative rheumatic diseases in clinical practice.

Scintigraphy (Planar)

Nuclear imaging provides not only morphologic but also physiologic information regarding the metabolic state of

tissues.^{237,238} Following injection of a radionuclide, gamma radiation emitted from the patient is captured by a gamma camera to generate a two-dimensional image. A wide range of radionuclides are available. The classical “bone scan” uses ^{99m}Tc chelated to diphosphonates (specifically, methylene diphosphonate [MDP]).^{237,238} Other compounds, such as ⁶⁷Ga citrate and ¹¹¹In WBC, are more specific for detecting inflammatory pathology, but their use must be dictated by a specific clinical setting in terms of relative costs and technical constraints. High sensitivity for active bone and joint pathology, high negative predictive value, and the ease of performing a whole body assessment (e.g., imaging Paget’s disease and metastatic disease) are the main advantages of scintigraphy. Low specificity, limited anatomic and spatial resolution (compared with plain radiography), use of ionizing radiation, and cost are the main weaknesses of this imaging technique.

In the evaluation of patients with arthritides, scintigraphy can be a useful adjunct to clinical assessment but should not be used routinely. Bone scans are more sensitive than conventional radiographs for detecting active bone pathology. In turn, MRI is usually more sensitive and specific than bone scintigraphy, with the added advantage of not using ionizing radiation.^{194,239,240} However, bone scintigraphy can provide a useful complementary role to MRI and other modalities for several clinical situations.

Single-Photon Emission Computed Tomography (SPECT)

SPECT is the generation of cross-sectional scintigraphic images produced by processing of multiple planar images obtained over a large range of camera positioning relative to the subject. The relationship of SPECT to planar scintigraphic imaging is analogous to the relationship between CT and plain radiography.

The use of SPECT has resulted in increased sensitivity and specificity compared with planar bone scintigraphy, especially in the assessment of spine pathology. Compared with planar scintigraphy, SPECT allows cross-sectional anatomic localization of active pathology (Figure 58-29). Tomographic reconstructions provide a more precise display of tracer accumulation, which helps to differentiate structures that overlap on planar images. This feature improves the specific diagnosis of conditions such as facet joint syndrome.²⁴¹

Poor anatomic and spatial resolution is the main limitation of conventional planar and SPECT bone scan images. However, newer SPECT/CT technology allows concurrent acquisition of a SPECT and a conventional CT study on the same machine, followed by fusion of their images (see Figure 58-29). This new modality combines the sensitivity of functional radionuclide images with the high spatial resolution and anatomic specificity of CT. A SPECT/CT study “maps” the functional abnormality demonstrated on a bone scan to an exact anatomic site on a CT scan. This improved anatomic specificity enhances the accuracy of cases in which the specific anatomic location of the lesion strongly influences the diagnosis. One common example is a small discrete lesion at a vertebral level, which is not visible on radiography or on CT but is clearly visible (active) on a

bone scan. Depending on other findings, the most likely diagnosis depends on its specific location: facet joint (arthritis), pars interarticularis (spondylolysis), or vertebral body (metastatic disease).

Positron Emission Tomography (PET)

Positron emission tomography (PET) is a functional imaging technique that enables metabolic mapping of the tissues in vivo with positron-emitting radionuclides. ¹⁸F-Fluorodeoxyglucose (¹⁸F-FDG) is the most commonly used radiopharmaceutical in PET because of its availability, favorable 110-minute half-life, and high uptake in most cancers. When injected into the body, ¹⁸F-FDG demonstrates sites of increased glucose metabolism, thus identifying sites of metabolically active pathology in both bone and soft tissue. A PET scan is inherently tomographic (cross-sectional), and it has a slightly higher spatial resolution than a SPECT scan. A “PET/CT” scan acquires both a PET and a CT scan concurrently on the same machine, allowing fusion of the two sets of images. Similar to SPECT/CT, the CT component of PET/CT provides a precise anatomic map superimposed on the (metabolic) PET images. ¹⁸F-FDG-PET (and/or PET/CT) is used mainly in oncology, where it has a well-established role in the diagnosis and clinical management of several malignancies, but it is also useful for a variety of clinical problems in cardiology, neurology, and infectious diseases. ¹⁸F-FDG-PET is now the test of choice for the assessment of fever of unknown origin.

PET can be useful for the diagnosis and management of osteomyelitis, Takayasu’s arteritis, and large vessel vasculitis occurring in patients with granulomatosis with polyangiitis (formerly Wegener’s granulomatosis), polyarteritis nodosa, giant cell arteritis, and polymyalgia rheumatic.^{18,242,243} FDG uptake is strongly correlated with MRI synovitis in RA,²⁴⁴ but its role, if any, for quantifying disease activity in inflammatory arthritides remains to be determined.

CONCLUSION

Imaging is an integral part of management of patients with rheumatic disease. This chapter has outlined the status of imaging in rheumatic disease, with a particular focus on inflammatory joint disease. Please see the Key Points for main messages. This chapter has explained the important role of conventional radiography, as well as the exciting new opportunities attainable with newer imaging techniques. The last decade has brought a vast amount of new knowledge that has markedly changed the way we manage our patients with rheumatic disease. It is exciting that with continued dedicated research and rapid technical development, it is likely that even larger improvements may occur in the decade to come, for the benefit of our patients.

Acknowledgments

The authors thank Drs. Anne Duer Jensen, Susanne Juhl Pedersen, Rene Poggenborg (all Copenhagen), Ali Guermazi (Boston), Ida Haugen (Oslo), and Fiona McQueen (Auckland) and Ho Jen (Edmonton) for providing images, and Trine Jensen David (Copenhagen), Ho Jen (Edmonton), and Pernille Bøyesen (Oslo) for critical review of parts of the text.

Figure 58-29 Gout (single-photon emission computed tomography [SPECT]). A 72-year-old female patient with known gout and prior trauma was investigated for possible complications. Planar (**A**) and transverse SPECT (**B**) images show multifocal increased uptake. Three-dimensional fused SPECT-CT (**C**) and transverse two-dimensional SPECT-CT (**D**) images provide superior localization of scintigraphic activity corresponding to the joints most affected by gout. Prostanoid Biology and Its Therapeutic Targeting

LESLIE J. CROFFORD

KEY POINTS

Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective anti-inflammatory, antipyretic, and analgesic compounds.

There is little difference in the efficacy of the various NSAIDs, but the pharmacologic characteristics of individual drugs including potency, half-life, and relative inhibition of cyclooxygenase (COX)-1 and COX-2 play important roles in toxicity.

Aspirin is an NSAID used in low doses to prevent cardiovascular disease. Aspirin and NSAIDs taken together are associated with increased toxicity in the gastrointestinal tract, and concomitant use of some NSAIDs with aspirin may be associated with aspirin resistance.

NSAIDs are associated with risk for gastrointestinal ulceration and bleeding. Patient-specific risk factors for gastrointestinal toxicity should be recognized in order to implement risk-reduction strategies.

NSAIDs are associated with an elevated risk for cardiovascular disease. Awareness of cardiovascular risk factors and either avoiding NSAIDs or using intermittent, low-dose, short half-life drugs are advisable.

Periodic assessment of blood pressure, hemoglobin, electrolytes, renal function tests, and liver function tests is advisable, particularly in elderly patients.

The use of nonsteroidal anti-inflammatory drugs (NSAIDs) is ubiquitous in the practice of medicine because of their effectiveness as anti-inflammatory, analgesic, and antipyretic agents. NSAIDs differ widely in their chemical class but share the property of blocking production of prostaglandins (PGs). This is accomplished by inhibiting the activity of the enzyme prostaglandin G/H synthase (PGHS), also called *cyclooxygenase* (COX).

The clinical effects of NSAIDs are evaluated not only by their specific pharmacologic properties but also in terms of their effects on the different COX isoforms, COX-1 and COX-2. These isoforms serve different biologic functions in that COX-1 is expressed under basal conditions and is involved in the biosynthesis of PGs serving homeostatic

functions while COX-2 expression is increased during inflammation and other pathologic situations. Inhibition of COX-2 by NSAIDs blocks PG production at sites of inflammation while inhibition of COX-1 in certain other tissues, most importantly platelets and the gastroduodenal mucosa, can lead to common adverse effects of NSAIDs such as bleeding, bruising, and gastrointestinal (GI) ulceration.

In addition to their use in rheumatoid arthritis and osteoarthritis, NSAIDs are widely used in the symptomatic management of other rheumatic diseases characterized by chronic musculoskeletal pain and diverse forms of acute pain. Aspirin, which has unique properties among NSAIDs, is used by millions more for primary and secondary prevention of cardiovascular thrombosis. In light of the widespread use of these drugs for common diseases, which are likely to increase in prevalence with the aging of the population, it is critically important to appreciate the potential adverse events and drug interactions associated with NSAIDs.

This chapter analyzes aspirin and other NSAIDs on the basis of chemical structure, pharmacologic properties, and relative inhibition of COX-1 and COX-2. Particular attention to potential adverse events of specific NSAIDs in individual patients will facilitate use of these drugs in the safest possible manner. Acetaminophen (known as *paracetamol* outside the United States), an antipyretic and analgesic drug without anti-inflammatory activity, inhibits COX enzymes by a different mechanism than NSAIDs and is also discussed. Colchicine possesses anti-inflammatory characteristics similar to NSAIDs in some situations and is discussed in this chapter, although this drug differs in its mechanism of action and profile of adverse effects.

HISTORY

Botanicals containing salicylates have been used since antiquity to treat pain, inflammation, and fever. The Egyptian Ebers papyrus recommended use of a decoction of dried myrtle leaves to be applied to the abdomen and back for relief of rheumatic pains about 3500 years ago. A thousand years later, Hippocrates recommended poplar tree juices for eye disease treatment and willow bark to alleviate fever and the pain of childbirth. Throughout Roman times, the use of

botanical treatments including willow bark for pain and inflammation was widespread. The medicinal use of salicylate-containing plants occurred in China and other parts of Asia. In addition, the curative effects of other botanicals were known to the indigenous populations of North America. Colchicine-containing extracts of the autumn crocus plant were used for treatment of acute gout as early as the sixth century AD.¹

The first modern report of the therapeutic application of salicylate-containing plants was reported to the Royal Society of London by the Reverend Edward Stone, who provided an account of the success of the dried bark of the willow for fever.¹ In this first “clinical trial,” a pound of bark was dried, pulverized, and put into the tea, beer, or water of 50 people with fever. He found that one dose (1 dram = 1.8 g) cured their fever. In 1763 Stone wrote, “I have no other motives for publishing this valuable specific, than that it may have a fair and full trial in all its variety of circumstances and situations, and that the world may reap the benefits accruing from it.”

In 1860 salicylic acid was chemically synthesized, which led to its widespread use as an external antiseptic, antipyretic, and analgesic.¹ The bitter taste of salicylic acid prompted the chemist Felix Hoffman to synthesize the more palatable acetylsalicylic acid (ASA). After demonstration of its anti-inflammatory effects, Dr. Heinrich Dreser of Bayer introduced this compound into medicine in 1899 as aspirin and it remains the most widely used drug in the world.¹ Salicylate was identified as the active ingredient of willow bark in 1929.

Phenylbutazone came into clinical practice in 1949 and was followed by indomethacin, fenamates, naproxen, and others. Despite the diversity of their chemical structures, these drugs shared therapeutic properties with aspirin. Furthermore, adverse events including gastric upset, GI ulceration and bleeding, hypertension, edema, and renal damage were shared by all these drugs. In 1971 it was discovered that these drugs all acted by inhibiting PG biosynthesis, thereby providing a unifying explanation of their therapeutic actions and a rationale for grouping them together as NSAIDs.¹

COX was isolated in 1976 from the endoplasmic reticulum of PG-forming cells.^{2,3} However, several groups speculated that there must be a second COX enzyme on the basis of observed biology. In 1990 investigators demonstrated that bacterial lipopolysaccharide (LPS) increased PG synthesis in human monocytes *in vitro* and in mouse peritoneal macrophages *in vivo*, but only the LPS-induced increase was inhibited by dexamethasone and required the *de novo* synthesis of “new” COX protein.⁴ This observation was the foundation of the concept for “constitutive” and “inducible” forms of COX. Soon thereafter a number of investigators working in different systems reported the discovery of an inducible second form of COX.³ Investigators went on to clone the gene and deduced its structure, and they found the gene product was homologous to COX, but to no other known protein. The observation that glucocorticoids inhibited the expression of COX-2 following a proinflammatory stimulus represented a link between the anti-inflammatory actions of NSAIDs and corticosteroids.

Because of the prediction that inhibiting COX-2 would block PG biosynthesis participating in the inflammatory

response but was not required for homeostasis, there was a tremendous push to develop drugs that specifically inhibit COX-2 without effect on COX-1 in the belief that these medications would provide clinical efficacy without adverse effects.^{2,5} Identification of new drugs that differentially inhibited COX-2 over COX-1 was accomplished quickly as existing NSAIDs were tested on the two COX isoforms and crystal structures revealed differences in the protein structures on which new drug development could be based.^{5,6}

One hundred years after aspirin was introduced and 10 years after the discovery of COX-2, selective COX-2 inhibitors, celecoxib (Celebrex) and rofecoxib (Vioxx), were developed. In clinical trials, the safety and efficacy profiles of these and related drugs showed promise and the U.S. Food and Drug Administration (FDA) subsequently approved these COX-2-selective NSAIDs for treatment of arthritis and pain. After the introduction into clinical practice, however, it became clear that the most highly COX-2-selective NSAIDs, particularly rofecoxib, were more likely than traditional NSAIDs to be associated with adverse cardiovascular events.⁷ This finding led to the voluntary withdrawal of rofecoxib and several other COX-2-selective NSAIDs from the market. Debate surrounding the relative risks of different NSAIDs to specific organ systems continues to the present.

CYCLOOXYGENASE BIOLOGY AND BIOACTIVE LIPIDS

Therapeutic and adverse effects of NSAIDs are best understood in the context of COX biology. The COX enzymes are the first committed step in the synthesis of PG from arachidonic acid (AA) (Figure 59-1). AA is an omega-6 polyunsaturated fatty acid (PUFA) commonly found at the *sn*-2 position of cell membrane glycerophospholipids and cleaved from cell membranes by one of several different phospholipase A₂ enzymes.⁸ Once generated, AA may enter several different pathways to generate bioactive lipids. It can be metabolized by COX to PGG₂ and then PGH₂ via its COX and peroxidase enzyme activities; by lipoxygenases (LOX) to hydroxyeicosatetraenoic acids (HETEs), hydroperoxyeicosatetraenoic acids (HPETEs), or leukotrienes; or by the cytochrome p450 family of enzymes to HETEs, HPETEs, or epoxyeicosatrienoic acids (EETs).^{9,10} These bioactive lipids have diverse biologic activities in normal physiology and in pathologic conditions including inflammation, pain, cardiovascular disease, and cancer.

In the COX pathway, the unstable intermediate PGH₂ spontaneously rearranges or is enzymatically converted by specific synthases to biologically active PG, of which there are many isoforms.³ Although phospholipase A₂ activity is required to initiate PG synthesis, the overall regulation of the type and amount of PG produced in a given cell or tissue is determined by the expression levels of COX-1, COX-2, and terminal synthase enzymes.

Bioactive lipids synthesized via the COX and LOX pathways are important mediators of inflammation, but alternate substrates and pathways can generate anti-inflammatory lipids and lipids important in the resolution of inflammation (Figure 59-2).^{11,12} Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which are omega-3 PUFAs, can

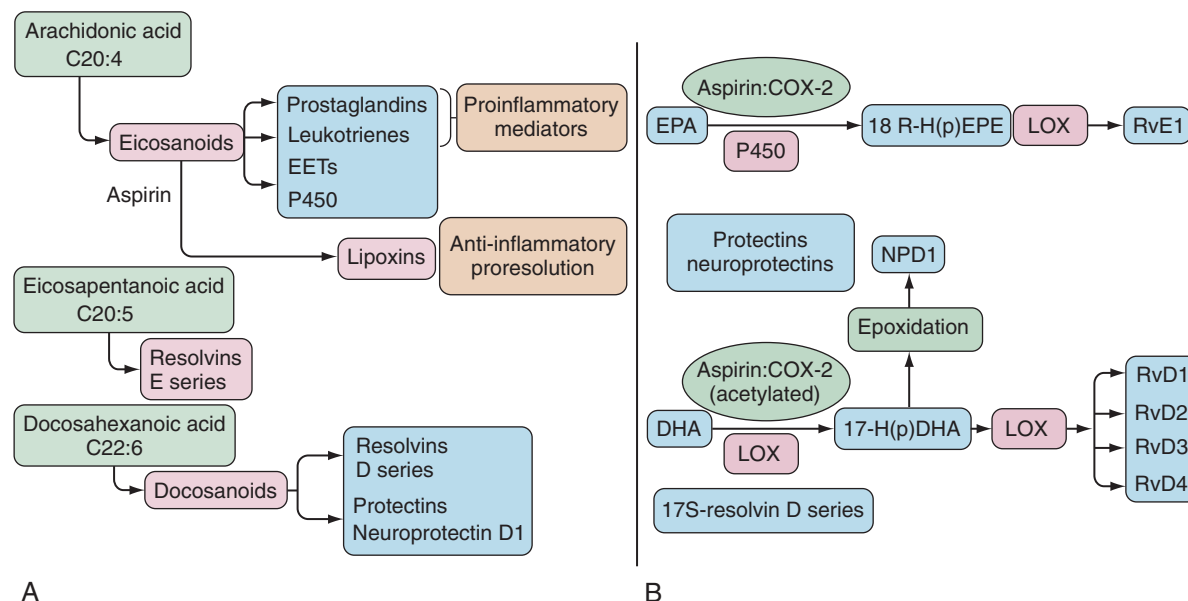

Figure 59-2 Biosynthesis of anti-inflammatory lipids. Function of essential polyunsaturated fatty acids in the production of families of bioactive lipid mediators. **A**, Arachidonic acid is the precursor of metabolites that function as proinflammatory mediators. Prostaglandins and leukotrienes play pivotal roles in the progression of inflammation. Through cell-cell interactions, exemplified by platelet leukocytes in the vasculature or polymorphonuclear cell-mucosa interactions, or both, lipoxins are generated. They serve as “stop signals” and promote resolution. They also serve as endogenous anti-inflammatory mediators self-limiting the course of inflammation. The essential omega-3 fatty acids eicosapentaenoic acid and docosahexaenoic acid (C20:5 and C22:6) are converted to new families of lipid mediators that are pivotal in promoting resolution (as in **B**). Resolvins of the E series such as RvE1 are generated from eicosapentaenoic acid, and resolvins of the D series such as RvD1 and the protectins such as neuroprotectin D1 (NPD1) are generated from docosahexaenoic acid, for which neural systems are enriched. **B**, Aspirin affects the formation of resolvin E1 by acetylating cyclooxygenase (COX)-2 in vascular endothelial cells, which, in a “stereoselective” way, can generate 18 R-H(p)EPE (hydroperoxyeicosapentaenoic acid), which is picked up through transcellular metabolism by leukocytes and converted by a lipoxygenase (LOX)-like mechanism to resolvin E1. Aspirin also affects the formation of D-series resolvins and catalytically switches COX-2 to a 17 R-LOX-like mechanism that serves to generate 17 R-series resolvin D. Aspirin also affects the formation of protectins and neuroprotectins by a similar mechanism and generates compounds carrying the 17 R epimer at the alcohol at carbon-17 in neuroprotectin D1 and other protectins. DHA, docosahexaenoic acid; H(p)DHA, hydroperoxydocosahexaenoic acid. (Modified from Serhan CN, Savill J: *Resolution of inflammation: the beginning programs the end*, Nat Immunol 6:1191–1197, 2005.)

important bioactive PGs are stably produced or their levels are increased when phospholipase activity and COX-2 levels are increased.

The actions of PG are mediated by cell surface G protein-coupled receptors (GPCRs). There are at least nine known PG receptors with additional splice variants (see Figure 59-1).¹⁷ The PG receptors belong to three clusters within a distinct subfamily of the GPCR superfamily with the lone exception of one of the PGD₂ receptors (DP₂), which belongs to the chemokine receptor subfamily. The *relaxant receptors* for prostacyclin (IP), PGD₂ (DP₁), and PGE₂ (EP₂ and EP₄) signal through G_s-mediated increases in intracellular cyclic adenosine monophosphate (cAMP). The *contractile receptors* for thromboxane A₂ (TP), PGF_{2α} (FP), and PGE₂ (EP₁) signal through a G_q-mediated increase in intracellular calcium. An *inhibitory receptor* for PGE₂ (EP₃) couples to G_i and decreases cAMP formation. Note that PGE₂ has at least four different receptors with a broad range of potential actions. EP₄ in particular appears to mediate many of the proinflammatory activities of PGE₂.¹⁸ Given the great diversity of PG receptors expressed by different cell types, PG signaling pathways constitute an enormously complex network controlling many biologic actions. Much work remains to understand fully all of the cellular signaling mechanisms by which PGs and their receptors elicit their respective biologic actions. This is particularly true as antagonists for many of these receptors show promise as novel targets for drug development.¹⁸

Biochemistry and Structural Biology

COX-1 and COX-2 are bifunctional enzymes that mediate a COX reaction whereby arachidonate plus two molecules of O₂ are converted to the cyclic endoperoxide PGG₂, followed by a hydroperoxidase reaction in which PGG₂ undergoes a two-electron reduction to PGH₂.⁸ COX enzymes are integral membrane proteins that sit within the inner leaflet of the lipid bilayer of intracellular phospholipid membranes of the nuclear envelope and the endoplasmic reticulum. The crystal structures of COX-1 and COX-2 have been solved, and they have essentially identical domain structures.⁶ The COX enzymes are homodimers with each monomer consisting of three structural domains. The N-terminal, epidermal growth factor-like domain is involved in dimerization via hydrophobic interactions. The membrane-binding domain is composed of four amphipathic α-helices lodged into half of the lipid bilayer to form a hydrophobic channel in the center of the large catalytic domain that contains the COX and peroxidase active sites and that constitutes about 80% of the protein. The catalytic domain is globular with two distinct intertwining lobes. The interface of these lobes creates a shallow cleft on the upper surface of the enzyme where the peroxidase active site is located and where heme is bound.

COX and hydroperoxidase reactions occur at distinct but structurally and functionally interconnected sites. The COX reaction is peroxide dependent and requires that the

heme group at the peroxidase site undergo a two-electron oxidation. A tyrosine residue (tyrosine 385) located at the COX active site is involved as a reaction intermediate. The physiologic heme oxidant *in vivo* is not known, but it has been shown that the COX activity of COX-2 can be activated at 10-fold lower concentrations of hydroperoxide than that of COX-1.⁸

NSAIDs function by blocking access of AA to the COX active site within a long, narrow, dead-end, hydrophobic channel whose entrance is framed by the four amphipathic helices of the membrane-binding domain. The channel extends into the globular catalytic domain and is about 8 Å wide. Significant narrowing of the channel occurs where arginine 120 protrudes into the channel. Arginine 120 is essential for binding both AA substrate and most carboxylate-containing NSAIDs in COX-1. By virtue of other differences in the hydrophobic channel, this residue is unessential for binding AA in COX-2, whereas it remains

critical for binding of most carboxylate-containing NSAIDs.^{19,20} Serine 530 is required for inhibition of COX by the phenylacetic acid NSAID diclofenac. Serine 530 is also the residue transacetylated by ASA and, along with valine 349, seems to govern the stereochemistry of the pocket such that after exposure to aspirin, AA is sterically blocked from a functional interaction with the catalytic domain in COX-1 and catalytic activity is completely inhibited.

A crucial structural difference between COX-1 and COX-2 is the substitution of the small amino acid valine in COX-2 for the isoleucine with a bulky side chain in COX-1 at position 523 that opens a side pocket in the hydrophobic channel in COX-2.⁶ Overall, COX-2 has a wider and somewhat more flexible interior channel, a structural feature that has been exploited with respect to the development of COX-2-selective NSAIDs as shown in Figure 59-3.²¹

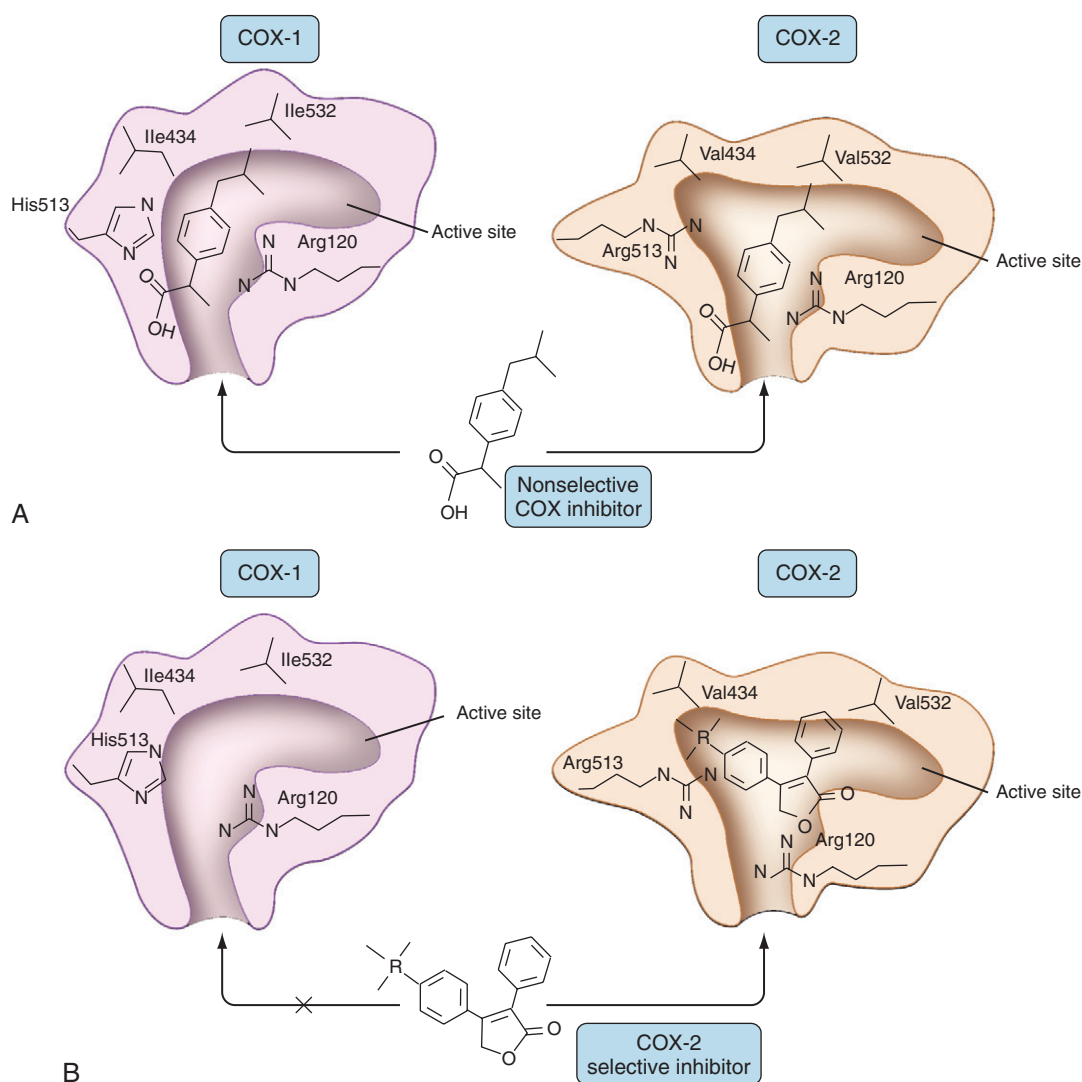

Figure 59-3 Cyclooxygenase (COX)-1 and COX-2 substrate-binding channels. Schematic depiction of the structural differences between the substrate-binding channels of COX-1 and COX-2 that allowed the design of selective inhibitors. The amino acid residues, Val434, Arg513, and Val523, form a side pocket in COX-2 that is absent in COX-1. **A**, Nonselective inhibitors have access to the binding channels of both isoforms. **B**, The more voluminous residues in COX-1, Ile434, His513, and Ile532, obstruct access of the bulky side chains of the coxibs. (From Grosser T, Fries S, FitzGerald GA: *Biological basis for the cardiovascular consequences of COX-2 inhibition: therapeutic challenges and opportunities*. J Clin Invest 116:4–15, 2006.)

Both enzymes are homodimers, but the monomers often behave asymmetrically as conformational heterodimers during catalysis and inhibition.²² That is, when a fatty acid binds to one monomer, the other monomer becomes catalytically active and only one monomer is catalytically active at any one time. The specific fatty acid bound to the non-catalytic monomer can regulate catalytic activity.²³ Different NSAIDs interact differently with respect to allosteric inhibition of COX enzymes as one facet of their pharmacology.²² ASA acetylation occurs in only one of the two COX monomers, which completely inhibits the activity of COX-1. However, COX-2 retains the ability to form a reduced amount of PGH₂ and alternate aspirin-triggered lipoxins from AA. The anti-inflammatory resolvins may be synthesized by ASA-acetylated COX-2 from omega-3 PUFA.²²

Molecular Biology

In addition to the differences in their structures relevant for the pharmacology of COX-1 and COX-2 inhibition, there are physiologically relevant differences with respect to expression and regulation.^{2,3} Generally, COX-1 is constitutively expressed in most cells and its expression is minimally altered by inflammatory stimuli. The promoter region of COX-1 has the characteristics of a gene that is continuously transcribed and stably expressed. COX-1 activity is regulated by substrate (AA) availability. When there is an increase in substrate mobilization via phospholipase A₂ activation, there is a concordant increase in PG synthesis mediated by COX-1. COX-1 is the only isoform expressed in mature platelets and is the most highly expressed COX isoform in normal gastroduodenal mucosa.²⁴ Because COX-1 is inhibited by nonselective NSAIDs, these physiologic properties may explain some of the common adverse effects of these drugs such as bleeding and GI ulceration.

In contrast, the COX-2 gene has the structure of a highly regulated product with binding sites for transcription factors such as nuclear factor κ B (NF κ B), cAMP-responsive element, and activating protein-1 (AP-1), which rapidly increase transcription in response to inflammatory signals.² COX-2 expression is highly induced by proinflammatory cytokines such as tumor necrosis factor and interleukin-1 β (IL-1 β), microbial products, and mitogens^{2,8} and is inhibited by glucocorticoids.² COX-2 mRNA stability is a key regulator of COX-2 levels. The potential for instability of the COX-2 message is due to the presence of multiple AUUUA instability sequences in the 3' region that mediate a rapid degradation of mRNA, which ultimately suppresses COX-2 protein synthesis and PG production. Conversely, some stimuli including IL-1 β may interfere with mRNA degradation and increase COX-2 levels and PG production.²⁵ COX-1 and COX-2 can be post-translationally modified. COX-1 is glycosylated at three asparagines involved in proper protein folding of the enzyme, whereas COX-2 can be glycosylated at four asparagines.^{25,26}

The generalization that COX-1 expression is constitutive and COX-2 expression is inducible has its limitations, given that COX-2 is expressed constitutively in several organ systems and regulated by physiologic, as well as pathologic, stimuli. COX-2 is basally expressed in the brain, kidney, pancreas, and blood vessels and therefore plays an

important role in normal reproductive, renal, cardiovascular, and skeletal physiology.^{2,21,27}

MECHANISM OF ACTION

Cyclooxygenase Inhibition

All of the NSAIDs are synthetic inhibitors of the COX active site, but subtle mechanistic differences in the manner in which individual NSAIDs interact and bind with the active site are responsible for some of the differences in their pharmacologic characteristics.²⁸ ASA is the only covalent, irreversible modifier of COX-1 and COX-2, whereas all of the other NSAIDs are competitive inhibitors, competing with AA for binding in the active site. The competitive inhibitors are subdivided further on the basis of whether they bind to the COX active site in a time-dependent or time-independent manner.

Crystallographic studies have shown how ASA effectively acetylates serine 530 of COX-1. Similar to other NSAIDs, ASA diffuses into the COX-1 active site at the mouth of the channel and travels to the constriction created by arginine 120, where it is in the best orientation to transacetylate serine 530, leading to the complete and irreversible inhibition of COX-1.²⁹ In COX-2, the channel of the active site is larger than COX-1, the orientation of ASA for serine 530 attack is not as good, and transacetylation efficiency for COX-2 is 10-fold to 100-fold less than for COX-1. ASA can also "trigger" COX-2 to alter its catalytic activity to produce 15 R-HETE and lipoxins from AA and to generate anti-inflammatory lipids from omega-3-PUFA.¹¹

The time it takes for an NSAID to inhibit the COX active site relative to how long it takes for it to leave the COX channel is a crucial factor in the inhibition of COX.³⁰ Drugs such as ibuprofen exhibit such rapid rates that they essentially inhibit COX instantly but can be removed from the COX active site just as quickly when drug levels decrease. Both COX monomers must be inhibited by ibuprofen to block catalytic activity.²² Conversely, indomethacin and diclofenac are time-dependent allosteric inhibitors that require seconds to minutes to bind to the COX active site and need only block one of the COX monomers to completely inhibit catalytic activity.²² These NSAIDs also need hours to exit the COX active site. Initially, most traditional time-dependent NSAIDs form a loose complex with the COX active site before a stronger interaction is established. This complex is limited by the time it takes the drug to become properly oriented within the COX channel at arginine 120, the constriction site in the COX channel. This may involve a change in conformation to the "open state" to allow the drug to access the upper part of the COX catalytic site.

Drugs such as flurbiprofen and indomethacin form a salt bridge between the carboxylate moiety of the NSAID and the guanidinium moiety of arginine 120. Hydrophobic interactions between the aromatic rings and the hydrophobic amino acids in the channel aid binding. Such interactions at the constriction point of the channel completely block the entry of substrate to the active site.³¹ Diclofenac interacts with serine 530, not arginine 120, but also blocks entry of substrate.³²

COX-2 Selectivity

NSAIDs such as meloxicam, nimesulide, and etodolac show some selectivity for inhibiting COX-2 over COX-1. After the discovery of COX-2, efforts to further enhance COX-2 selectivity led to the development of celecoxib, rofecoxib, valdecoxib, etoricoxib, and lumiracoxib. The prototypical COX-2-selective NSAIDs, celecoxib and rofecoxib, are diaryl compounds containing a sulfonamide (celecoxib) and methylsulfone (rofecoxib) rather than a carboxyl group. Both drugs are weak time-independent inhibitors of COX-1 but strong time-dependent inhibitors of COX-2 that require their entry into and stabilized binding in the catalytic pocket. Because these drugs lack a carboxyl group, arginine 120 is not involved, but multiple sites of hydrogen and hydrophobic binding stabilize drugs at the catalytic site. The sulfur-containing phenyl ring of COX-2-selective NSAIDs plays a pivotal role in binding stability by occupying the hydrophobic side pocket characteristic of the COX-2 catalytic site. If this side pocket is removed by mutagenesis, all isozyme selectivity is lost.⁶

COX isozyme selectivity is defined most commonly using the concentration of drug required to inhibit PG production by 50% in a particular assay system (inhibitory concentration, or IC₅₀). Ratios using values obtained for COX-1 IC₅₀s compared with COX-2 IC₅₀s can be calculated and used as a standard measure for comparing the degrees of selectivity of a particular NSAID for one or the other COX isoform.³³ PG assay systems can vary widely, however, making it difficult to compare directly results from studies using different assay systems. To circumvent such problems, most clinicians have accepted the use of the *in vitro* whole-blood assay to compare NSAID selectivities. In this system, COX-1 inhibition is assessed as a function of the reduction of thromboxane made by platelets after clot formation. Inhibition of COX-2 is based on the inhibition of PGE₂ production in a heparinized blood sample after LPS stimulation. A COX-2-selective NSAID lacks inhibitory effect on platelet COX-1 at concentrations at or above those that maximally inhibit COX-2.^{5,34}

Cyclooxygenase-Independent Mechanisms of Action

At high, nonphysiologic concentrations, some NSAIDs seem to elicit effects on cellular pathways *in vitro* that do not involve the inhibition of COX. Because of the high doses of drug required and the use of *in vitro* systems, the relevance of these effects to *in vivo* activity is uncertain. Some NSAIDs inhibit phosphodiesterases associated with the metabolism of cAMP leading to increased intracellular cAMP levels and the subsequent general inhibition of peripheral blood lymphocyte responses to mitogen stimulation, monocyte and neutrophil migration, and neutrophil aggregation.³⁵ NSAIDs scavenge free radicals, inhibit superoxide production by polymorphonuclear neutrophils, reduce mononuclear cell phospholipase C activity, and inhibit inducible nitric oxide synthase activity. Sodium salicylate and ASA inhibit NFκB activation, as do certain inactive enantiomers of flurbiprofen. Some reports indicate that other cell signaling molecules such as mitogen-activated protein kinases and the transcription factor AP-1 may also

be modulated by NSAIDs. Some NSAIDs bind to and activate members of the peroxisome proliferator-activated receptor (PPAR) family and other intracellular receptors. PPAR activation is thought to mediate anti-inflammatory activities. Selective COX-2 inhibitors may have unique structural features that promote COX-independent activities such as cell-cycle regulation, apoptosis, and antiangiogenesis.³⁶

Mechanism of Acetaminophen and Other Analgesic Antipyretic Drugs

Acetaminophen (paracetamol) and dipyron relieve pain and fever, but they are not anti-inflammatory. The precise mechanisms by which these drugs elicit their effects remain unclear. In the 1970s, it was proposed that acetaminophen worked by means of a “central” action by inhibiting COX activity primarily in the brain and not in peripheral tissues because they were not acidic and could cross the blood-brain barrier.³⁷ Acetaminophen does inhibit COX-1 and COX-2, but variably so and dependent on cell and tissue type. Acetaminophen does not appear to inhibit by interaction with the COX active site; rather, it serves as a reducing co-substrate for the peroxidase site. The peroxide tone of cells and tissues *in vivo* may be responsible for inhibitor specificity, with platelets and activated macrophages being resistant to the action of acetaminophen and vascular endothelial cells being sensitive to its inhibitory effects on COX. Additionally, the inhibitory potency of acetaminophen is determined by the concentration of the COX enzyme.³⁷ This may be an additional factor for the lack of clinical anti-inflammatory effects because inflammation is associated with a markedly increased expression of COX-2 enzyme. With the discovery of a COX-1 splice variant and studies showing that it is both highly expressed in brain and more sensitive to inhibition by acetaminophen, some authors proposed that the analgesic and antipyretic actions of acetaminophen could be explained by its ability to inhibit the COX-1 splice variants (called COX-3 by some despite the fact that this variant does not arise from a unique gene).³⁸ However, more recent studies have rejected this mechanism as explanatory for acetaminophen effects.^{37,39}

Salicylate has analgesic, antipyretic, and anti-inflammatory activity but, similar to acetaminophen and in contrast to ASA, is a poor COX inhibitor. Salicylate has also been shown to inhibit COX activity if substrate levels are low, and it is also dependent on the oxidative state of the enzyme, suggesting that this drug may inhibit COX by redox-related mechanisms.⁴⁰

PHARMACOLOGY AND DOSING

Classification

NSAIDs are generally grouped according to their chemical structures, plasma half-life, and COX-1 versus COX-2-selectivity (Table 59-1 and Figure 59-4). Table 59-1 presents a representative compilation of common NSAIDs, formulations, dosages, half-lives, and precautions. Structurally, most NSAIDs are organic acids with low pK values that lend themselves to their accumulation at sites of inflammation,

Table 59-1 Common Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Drug	Brand Name	Available Formulations (mg)	Maximal Daily Dose (mg)	Tmax (hr)	Half-life (hr)	Dose Adjustment or Special Precautions
Salicylic Acids						
Acetylsalicylic acid	Aspirin	Tablets: 81,165, 325, 500, 650 Children's: 81 Suppository: 120, 200, 300, 600	3000	0.5	4-6	Decrease dose by 50% in renal failure patients and patients with hepatic insufficiency
Salsalate	Disalcid Amigesic Salflex	Capsule: 500 Tablet: 500, 750	3000	1.4	1	
Diflunisal	Dolobid	Tablets: 250, 500	1500	2-3	7-15	
Acetic Acids						
Diclofenac	Voltaren Voltaren XR Cataflam	Tablets: 25, 50, 75 Extended release: 100	225	1-2	2	Incidence of increased transaminase levels higher than with other NSAIDs
Diclofenac + misoprostol	Arthrotec	Tablets: 50 or 75 plus misoprostol 200 µg	200	1-2	2	Incidence of increased transaminase levels higher than with other NSAIDs
Indomethacin	Indocin	Caps: 25, 50	200	1-4	2-13	Approved for treatment of patent ductus arteriosus
	Indocin SR	Sustained release: 75 Oral suspension: 25 mg/5 mL Suppositories: 50				
Sulindac	Clinoril	Tablets: 150, 200	400	2-4	16	Prodrug metabolized to active compound Decrease dose in renal disease, liver disease, and elderly patients
Ketorolac	Toradol	IM/IV: 15 or 30 mg/mL	120 IV/IM	0.3-1	4-6	Decrease dose by 50% in renal failure and elderly patients Do not use > 5 days
Tolmetin	Tolectin	Tablets: 10 Tablets: 200, 600 Caps: 400	40 mg PO 1800	0.5-1	1-1.5	
Etodolac	Lodine Lodine XL	Caps: 200, 300 Tablets: 400 Extended release: 400, 500, 600	1200	1-2	6-7	
Propionic Acids						
Ibuprofen	Motrin Advil Nupren Rufen	Tablets: 200 (OTC), 300, 400, 600, 800	3200	1-2	2	Avoid in severe hepatic disease
Naproxen	Naprosyn	Tablets: 125 (OTC), 250, 375, 500 Sustained release: 375, 500 Suspension: 125 mg/5 mL	1500	2-4	12-15	Decrease dose in renal disease, liver disease, and elderly patients
	Aleve Anaprox EC-Naprosyn Naprelan Nalfon					
Fenoprofen		Caps: 200, 300, 600	3200	1-2	2-3	Idiosyncratic nephropathy more frequent than with other NSAIDs
Ketoprofen	Orudis Oruvail	Tablets: 12.5 (OTC) Caps: 25, 50, 75 Sustained release: 100, 150, 200	300	0.5-2	2-4	Decrease dose in severe renal disease, hepatic disease, and elderly patients
Flurbiprofen Oxaprozin	Ansaid Daypro	Tablets: 50, 100 Tablets: 600	300 1800 or 26 mg/kg/day	1.5-2 3-6	3-4 49-60	Decrease dose in renal failure patients and patients < 50 kg
Fenamic Acids						
Meclofenamate	Meclomen	Caps: 50, 100	400	0.5	2-3	
Oxicams						
Piroxicam	Feldene	Caps: 10, 20	20	2-5	3-86	Decrease dose in hepatic disease and elderly patients
Meloxicam	Mobic	Tab: 7.5, 15	15	5-6	20	
Nonacidic Compounds						
Nabumetone	Relafen	Tablets: 500, 750	2000	3-6	24	Food increases peak concentration Reduce dose in renal disease Avoid in severe liver disease Limit dose to 1 g/day in elderly patients

Table 59-1 Common Nonsteroidal Anti-inflammatory Drugs (NSAIDs)—cont'd

Drug	Brand Name	Available Formulations (mg)	Maximal Daily Dose (mg)	T _{max} (hr)	Half-life (hr)	Dose Adjustment or Special Precautions
COX-2 Selective Inhibitors						
Celecoxib	Celebrex	Caps: 100, 200, 400	400 (800 mg in FAP)	3	11	Contraindicated with sulfonamide allergy
Etoricoxib*	Arcoxia	Tablets: 60, 90, 120	120	1-1.5	22	Contraindicated in severe renal or liver disease patients Caution in mild-to-moderate disease

FAP, familial adenomatous polyposis; IM/IV, intramuscular/intravenous; OTC, over the counter; PO, Oral.

areas that often exhibit lower pHs than uninvolved sites. Most often, there is a direct relationship between low pK and short half-life, but there are exceptions such as nabumetone, which is nonacidic. Classifying NSAIDs on the basis of plasma half-life can be problematic given the fact that these drugs tend to accumulate in synovial fluid, where the concentration of drug may remain more stable than in the plasma. Short half-life NSAIDs potentially could be given less frequently than indicated by their plasma half-life. NSAIDs exhibiting longer half-lives require more time to reach steady-state plasma levels. Drugs with a half-life greater than 12 hours can be given once or twice a day. Plasma levels increase for a few days to several weeks

(depending on the specific half-life) but then tend to remain constant between doses. NSAIDs with longer half-lives also enable drug concentrations to equilibrate between the plasma and the synovial fluid, though total bound and unbound drug levels are usually lower in synovial fluid because there is less albumin in synovial fluid than in plasma. However, NSAIDs with longer half-lives or extended release formulation may be associated with increased propensity to cause adverse effects.⁴¹ COX-isozyme selectivity is likely to be a critically important factor in determining relative GI and cardiovascular risk, which should also be considered in addition to other pharmacologic properties for each NSAID.³³

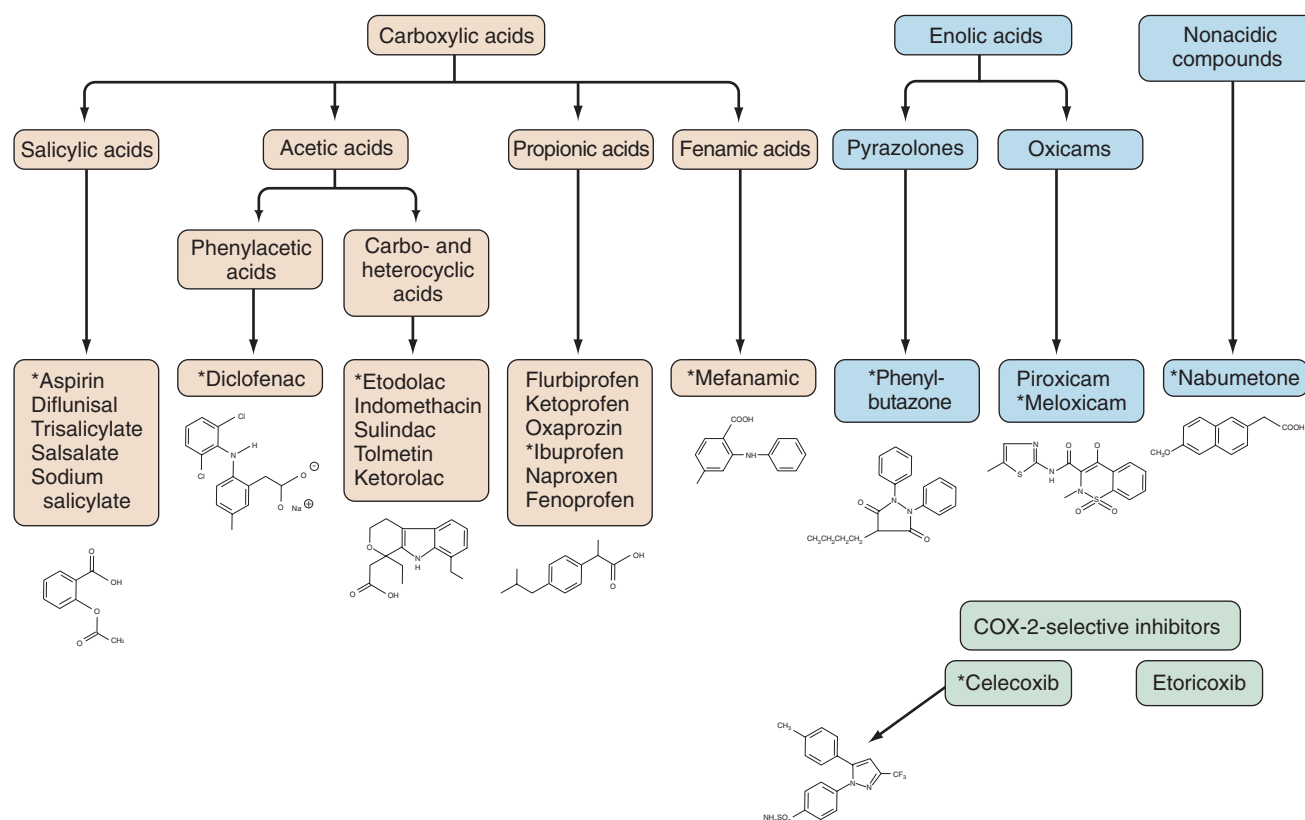

Figure 59-4 Classification and representative structures of the traditional nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2)-selective NSAIDs. NSAIDs. *Selected NSAID structure from each subclass.

NSAID Metabolism

Almost all NSAIDs are more than 90% bound to plasma proteins. If total drug concentrations are increased beyond the point at which the binding sites on albumin are saturated, biologically active free drug concentrations increase disproportionately to the increasing total drug concentration. The clearance of NSAIDs is usually by hepatic metabolism with production of inactive metabolites that are excreted in the bile and urine. Most NSAIDs are metabolized through the microsomal cytochrome P450-containing mixed-function oxidase system. NSAIDs are most often metabolized by CYP3A, CYP2C9, or both. However, some are metabolized by other cytosolic hepatic enzymes.

Salicylate Metabolism and Aspirin Resistance

Salicylates are acetylated (e.g., aspirin) or nonacetylated (e.g., sodium salicylate, choline salicylate, choline magnesium trisalicylate, salicylsalicylic acid).⁴⁰ Although the nonacetylated salicylates are only weak inhibitors of COX *in vitro*, they are able to reduce inflammation *in vivo*. Aspirin is rapidly deacetylated to salicylate, both spontaneously and enzymatically. Differences in formulation of these agents affect the absorption properties, but not bioavailability. Buffered aspirin tablets contain antacids that increase the pH of the microenvironment, whereas enteric coating slows absorption. The bioavailability of rectal aspirin suppositories increases with retention time. Salicylates primarily bind to albumin and rapidly diffuse into most body fluids. Salicylate is metabolized principally by the liver and excreted primarily by the kidney. In the kidney, salicylate and its metabolites are freely filtered by the glomerulus, then reabsorbed and secreted by the tubules. Salicylate serum levels usually do not correlate well with dosage, however, and small increases in dosage may result in disproportionate increases in serum levels. The drug clearance rate is a function of serum concentration. The primary factors regulating serum salicylate levels are urinary pH and metabolic enzyme activity.

The term “aspirin resistance” is broadly used to describe the failure of aspirin to prevent a thrombotic event whether due to pharmacologic resistance to the antiplatelet effects of aspirin or due to the inability of aspirin to overcome thrombophilia in a given clinical setting.⁴² Factors such as sex, genetic polymorphisms, and clinical factors including smoking, obesity, and diabetes may alter aspirin effects on platelet function. Lack of adherence and drug interactions also may play a role in aspirin resistance.

Pharmacologic Variability

Different patients can respond to the same NSAID in a variety of ways, and the basis for this individual variability remains unclear. Several pharmacologic factors related to NSAIDs may influence this variability such as dose response, plasma half-life, enantiomeric conversion, urinary excretion, and pharmacodynamic variation.⁴³ Other important drug factors include protein binding, the metabolic profile of the drug, and the percentage of the drug that is available as the active (*S*) enantiomer. Some NSAIDs exist as two enantiomers; these include the propionic acid derivatives

ibuprofen, ketoprofen, and flurbiprofen, which exist as mixtures of inactive (*R*) and active (*S*) enantiomers. Naproxen is composed of the active (*S*) enantiomer. Conversion of the propionic acid NSAIDs from the inactive (*R*) enantiomer to the active (*S*) enantiomer occurs *in vivo* to various degrees, providing some basis for the variability in patient response. There is also genetic variability in the cytochrome P450 metabolic enzymes such that some individuals or ethnic groups metabolize drugs more slowly. For example, Asians are frequently slow metabolizers through the CYP2C9 pathway. Finally, the pharmacokinetics of some NSAIDs are affected by hepatic disease, renal disease, or old age.

Routes of Drug Delivery

NSAIDs are produced in a variety of dosage forms including intravenous, slow-release and sustained-release oral preparations, topical preparations in various forms including gels and patches, and suppositories. Given the desire to reduce NSAID toxicity while preserving drug delivery to a specific site, efforts continue to alter drug formulation and delivery systems. Nanoparticles, liposomes, and microspheres are under investigation to allow dose reduction and specific targeting. Intra-articular delivery is under consideration, but because joints have efficient lymphatic clearance systems, the utility of this form of targeting remains to be proved.

Topical NSAID formulations were developed to reduce systemic exposure while preserving efficacy. Diclofenac, for example, is available as a solution, gel, or patch. The systemic effects are directly proportional to the surface area, and this method of delivery results in a relatively stable systemic diclofenac level compared with oral administration.⁴⁴

Combination Drugs

NSAIDs have also been combined with agents having gastroprotective effects into “polypills” that are currently available on the market. This strategy may increase compliance with effective protective agents, thereby reducing adverse effects in clinical practice. Combining diclofenac with the synthetic PGE₁ analogue misoprostol (Arthrotec) is shown to reduce risk of NSAID-related peptic ulcerations and mucosal injury, but utility of the combination is often limited by misoprostol-induced cramping and diarrhea.⁴⁵ In population-based studies, Arthrotec was more effective than diclofenac and misoprostol co-prescription in preventing hospitalization for peptic ulcer disease or GI hemorrhage.⁴⁶ The combination of enteric-coated naproxen and the proton pump inhibitor (PPI) esomeprazole (Vimovo) into a single pill has been approved by the U.S. Food and Drug Administration. This agent was shown to reduce endoscopically detected gastric ulcers.⁴⁷

A different strategy is nitric oxide releasing NSAIDs (NO-NSAIDs), which are synthesized by the ester linkage of an NO-releasing moiety to conventional NSAIDs including aspirin, flurbiprofen, diclofenac, sulindac, and others.⁴⁸ The NO moiety is slowly released by enzymatic activity *in vivo*, likely by esterases, resulting in slow accumulation of the parent NSAID. The lower rate of GI ulceration

associated with these drugs is likely related to NO-associated vasodilation and the relatively lower concentration of the parent NSAID.

THERAPEUTIC EFFECTS

Anti-inflammatory Effects

NSAIDs are frequently used as first-line agents for the symptomatic relief of many different inflammatory conditions. In double-blind, randomized clinical trials of inflammatory arthritis, NSAIDs have been compared with placebo, aspirin, and each other. Clinical trials of NSAID efficacy in rheumatoid arthritis (and osteoarthritis) most often employ a design whereby the current NSAID is discontinued and the patient must have an increase in symptoms or flare to enter the study. Although there is some variation in primary outcome measures, most include parameters that make up the American College of Rheumatology (ACR)-20. Efficacy superior to that of placebo is easily demonstrated for NSAIDs within 1 to 2 weeks in patients with active RA who are not receiving corticosteroids or other anti-inflammatory medications.⁴⁹ Comparisons of adequate doses of traditional NSAIDs or COX-2-selective NSAIDs with one another almost always show comparable efficacy. Despite improvement in pain and stiffness with NSAIDs, these agents do not usually reduce acute phase reactants, nor do they modify radiographic progression. The anti-inflammatory effects of NSAIDs have also been demonstrated in rheumatic fever, juvenile rheumatoid arthritis, ankylosing spondylitis, gout, osteoarthritis, and systemic lupus erythematosus (SLE). Although not as rigorously proven, their efficacy is also accepted in treatment of reactive arthritis, psoriatic arthritis, acute and chronic bursitis, and tendinitis.

Analgesic Effects

Virtually all NSAIDs relieve pain when used in doses substantially lower than those required to suppress inflammation. The analgesic action of NSAIDs is due to inhibition of PG production in peripheral tissues and in the central nervous system (CNS). In the periphery, PGs do not induce pain per se but rather sensitize peripheral nociceptors to the effects of mediators such as bradykinin or histamine.⁵⁰ PGs released during inflammation or other trauma lower the activation threshold of tetrodotoxin-resistant sodium channels on sensory neurons. In the CNS, where NSAIDs and acetaminophen exert analgesic effects, PGs also play an important role in neuronal sensitization. COX-2 is constitutively expressed in the dorsal horn of the spinal cord, and its expression is increased during inflammation.⁵¹ Centrally generated PGE₂ activates spinal neurons and also microglia that contribute to neuropathic pain.⁵² Both COX-1 and COX-2 play a role in nociception as demonstrated by reductions in experimental pain in mice deficient in either COX-1 or COX-2.⁵³

Antipyretic Effects

The NSAIDs and acetaminophen effectively suppress fever in humans and experimental animals. Fever results from the

production of PG, primarily PGE₂, from vascular endothelial cells via COX-2 and mPGES-1.⁵⁴ These PGs generate neuronal signals that activate the thermoregulatory center in the preoptic area of the anterior hypothalamus. PGE₂ synthesis is stimulated by endogenous (e.g., interleukin-1) or exogenous (e.g., lipopolysaccharide) pyrogens. Mice with a targeted deletion of either the COX-2 or mPGES-1 genes fail to develop fever in response to inflammatory stimuli.⁵⁵

Little evidence suggests that any NSAID has superior efficacy as an antipyretic. However, in fever associated with viral illnesses, aspirin should be avoided due to the association with hepatocellular failure (Reye's syndrome).⁵⁶

Other Therapeutic Effects

Antiplatelet Effects

Aspirin and traditional NSAIDs inhibit platelet COX-1 to variable degrees. Except for aspirin, inhibition of platelet aggregation is reversible and depends on the concentration of drug in the platelet. Aspirin acetylates platelet COX-1, which cannot be resynthesized. The antiaggregation effect of as little as 80 mg of aspirin can last for up to 4 to 6 days, until the bone marrow can synthesize new platelets.⁵⁷

On the basis of accumulated data showing its benefits, the FDA has approved ASA for use in the secondary prevention of cardiovascular disease. Major trials have shown that meaningful decreases in nonfatal myocardial infarction (MI), nonfatal stroke, and death can be realized by daily administration of ASA of 75 to 325 mg. Major vascular events can be reduced by 10 to 20 events for every 1000 patients treated, at a cost of one to two major GI bleeds.⁵⁸

There was no reduction in rates of MI observed with the use of ASA, 100 mg every other day, in the Nurses Health Study of primary prevention of major vascular events, whereas rates of GI bleeding were increased. However, stroke rates were significantly reduced on this regimen.⁵⁹ The U.S. Preventative Health Task Force has updated its recommendations to encourage use of low-dose ASA in men aged 45 to 79 and women aged 55 to 79.⁵⁸ ASA used for primary prevention of cardiovascular events appears to lower the risk for MI in men and for stroke in women.⁶⁰

Cancer Chemoprevention

A large body of epidemiologic and animal studies provides evidence that a high-fat diet can be associated with a risk for cancer. AA, one of the major ingredients of animal fats, and the eicosanoids derived from AA are shown to be important contributors to cancer development.¹⁰ Large-scale epidemiologic studies have long indicated that long-term NSAID use reduces the incidence of a variety of cancers including colon, intestinal, gastric, breast, and bladder, 40% to 50%.¹⁰ Given the ability of the NSAIDs to inhibit COX and PG production, the COX pathway immediately becomes implicated as playing an important role in the pathogenic process. It is well recognized that growth factors, tumor promoters, and oncogenes stimulate PG production via the induction of COX-2 and that human tumorigenic tissues exhibit increased COX activity compared with their normal, nontumorigenic counterparts. COX-2 is overexpressed in 80% of colorectal cancer tissues. Among

the PGs, PGE₂ is most abundant in human neoplasms. The inducible mPGES-1 enzyme is highly expressed in tumors, and its absence suppresses intestinal tumorigenesis in animal models. Furthermore, the enzyme that metabolizes intracellular PGE₂, 15-hydroxyprostaglandin dehydrogenase, is ubiquitously lacking in tumors, and mice with a genetic deletion of this enzyme have accelerated tumorigenesis.¹⁰ Many natural products including resveratrol (red wine), catechins (green tea), and curcumin (saffron) also inhibit COX, which may be an important mechanism underlying their putative cancer-preventing effects.⁶¹

A retrospective cohort study shows that aspirin and traditional NSAIDs specifically reduce cancer risk in the subgroup of patients whose colon tumors express higher levels of COX-2.⁶² In a meta-analysis of ASA (75 mg daily and upward without dose dependence) effects on cancer, allocation to aspirin reduced death due to cancer by more than 20%.⁶³ On analysis of individual patient data, cancer death benefit was apparent only after 5 years' follow-up, and benefit increased with scheduled duration of trial treatment. ASA effects appear greater on adenomatous cancer than other cancer types. Other studies demonstrated a reduction in both incidence of colorectal cancer and death from colorectal cancer, particularly for cancers of the proximal colon.⁶⁴ Long-term low-dose ASA use also appears to reduce the risk of prostate cancer.⁶⁵

Clinical trials also demonstrated that traditional and COX-2-selective NSAIDs could cause regression of polyps in patients with familial adenomatous polyposis (FAP).⁶⁶ Celecoxib was subsequently approved by the FDA for reduction of polyps in patients with FAP. Although NSAIDs are still among the most promising chemopreventative agents for cancer, cardiovascular and GI side effects have dampened enthusiasm.¹⁰ Alternative strategies for blocking effects of PGE₂ and other eicosanoids need evaluation to determine their effectiveness as cancer prevention and adjunct therapy.

ADVERSE EFFECTS

The NSAIDs share a common spectrum of clinical toxicities, although the frequency of particular side effects varies with the compound (Table 59-2). Hazard of individual NSAIDs is related to the pharmacologic characteristics such as bioavailability and half-life, as well as potency for inhibition of COX-1 and COX-2.^{33,41,67}

Gastrointestinal Tract Effects

NSAIDs cause GI injury through both topical and systemic effects. Following mucosal injury, NSAIDs inhibit the early events necessary to repair superficial injury, as well as later events of cell proliferation and angiogenesis leading to delayed ulcer healing.⁶⁸ Topical injury initiates the initial mucosal erosions by disrupting the gastric epithelial cell barrier, but PG depletion is essential for the development of clinically significant gastric and duodenal ulcers. The propensity of specific NSAIDs to cause acute topical injury depends on the pKa, with most NSAIDs being weak organic acids. Aspirin is particularly prone to cause mucosal injury when administered orally.²⁴ Nonacidic NSAIDs such as nabumetone, etodolac, and celecoxib do not cause acute

Table 59-2 Shared Toxicities of Nonsteroidal Anti-inflammatory Drugs

Organ System	Toxicity
Gastrointestinal	Dyspepsia Esophagitis Gastroduodenal ulcers Ulcer complications (bleeding, perforation obstruction) Small bowel erosions and strictures Colitis
Renal	Sodium retention Weight gain and edema Hypertension Type IV renal tubular acidosis and hyperkalemia Acute renal failure Papillary necrosis Acute interstitial nephritis Accelerated chronic kidney disease
Cardiovascular	Heart failure Myocardial infarction Stroke Cardiovascular death
Hepatic	Elevated transaminases Reye's syndrome (aspirin only)
Asthma/allergic	Aspirin-exacerbated respiratory disease* (susceptible patients) Rash
Hematologic	Cytopenias
Nervous	Dizziness, confusion, drowsiness Seizures Aseptic meningitis
Bone	Delayed healing

*Reduced risk in COX-2-selective nonsteroidal anti-inflammatory drugs.

mucosal lesions. Esterification of acidic NSAIDs such as the case for NO-NSAIDs suppresses mucosal injury.²⁴

Acidic NSAIDs accumulate in gastric epithelial cells and lead to generation of reactive oxygen species. NSAIDs may also cause apoptosis, which appears independent of COX inhibition. They also associate with extracellular phospholipids resulting in attenuation of the hydrophobic surface barrier of the stomach.⁶⁹ Phospholipids associated with cell membranes are disrupted, leading to increased permeability and acid or bile back diffusion.

The integrity of mucosal defense depends on generation of PGE₂ and PGI₂ from COX enzymes. COX-1 is abundantly expressed under basal conditions in gastric mucosa, whereas COX-2 is almost undetectable. However, both COX-1 and COX-2 are rapidly upregulated following injury or when there are pre-existing ulcers.⁷⁰ This may explain the observation that concurrent *Helicobacter pylori* infection increases the risk of developing peptic ulcers and increases bleeding in NSAID users.⁷¹

It appears that concurrent COX-1 and COX-2 inhibition is associated with the highest propensity to develop gastric ulcers.⁴¹ This clinical observation is consistent with animal studies whereby mice deficient for a single COX enzyme or treated with drugs that specifically inhibit either COX-1 or COX-2 do not develop ulceration. Severe gastric lesions are seen when both enzymes are simultaneously blocked. However, when gastric mucosa is damaged, inhibition of either COX-1 or COX-2 is associated with development of ulcers.⁶⁸ Traditional and COX-2-selective NSAIDs delay ulcer healing, with nonselective NSAIDs doing so to a

Figure 59-5 Established risk factors for upper gastrointestinal bleeding associated with nonsteroidal anti-inflammatory drug (NSAID) use. OR, odds ratio; RR, relative risk. (Adapted from Gutthann SP, García-Rodríguez LA, Raiford DS: *Individual non-steroidal anti-inflammatory drugs and other risk factors for upper gastrointestinal bleeding and perforation*, *Epidemiology* 8:18–24, 1997; Huang JQ, Sridhar S, Hunt RH: *Role of Helicobacter pylori infection and non-steroidal anti-inflammatory drugs in peptic ulcer disease: a meta-analysis*, *Lancet* 359:14–22, 2002; and Lanas A, García-Rodríguez LA, Arroyo MT, et al: *Risk of upper gastrointestinal ulcer bleeding associated with selective cyclooxygenase-2 inhibitors, traditional non-aspirin non-steroidal anti-inflammatory drugs, aspirin and combinations*, *Gut* 55:1731–1738, 2006.)

greater degree.⁷² It should also be noted that GI bleeding may be related to the combination of injury and inhibition of platelet aggregation. This is an additional factor in the propensity of aspirin and other nonselective NSAIDs to cause clinically apparent ulcers.^{24,68}

Dyspepsia

Nonulcer dyspepsia is the most common adverse event (10% to 20%) associated with use of NSAIDs and may account for poor tolerability.⁷³ Dyspepsia is more often reported in younger as compared with older patients.⁷⁴ Though expected to reduce dyspepsia, COX-2-selective NSAIDs are also associated with a substantial level of adverse GI symptoms.⁷³ PPIs have been shown to reduce dyspepsia in controlled trials.⁷⁴ Studies have shown that histamine-2-receptor antagonists (H₂RAs) are also effective for reducing dyspepsia.⁷⁵ Crucially from a clinical perspective, subjective symptoms of dyspepsia, fecal blood loss, and endoscopic findings correlate poorly. Furthermore, only a minority of patients with serious GI events report antecedent dyspepsia.⁷⁶

Gastritis and Gastroduodenal Ulcer

Up to 25% of chronic NSAID users will develop ulcer disease, and 2% to 4% will bleed or perforate. These GI events result in more than 100,000 hospital admissions annually in the United States and between 7000 and 10,000 deaths, especially in those patients with highest risk.⁴⁵ The risk for ulcer complications appears highest within the first 3 months of use but remains present with longer-term therapy. A recent meta-analysis of observational studies on NSAIDs and upper GI bleeding or perforation of studies published between 2000 and 2008 demonstrated a relative risk of 4.50 (95% confidence interval [95% CI], 3.82 to 5.31) for traditional NSAIDs and 1.88 (95% CI, 0.96 to 3.71) for selective COX-2 inhibitors.⁴¹ For traditional NSAIDs, the risk of low or medium doses was associated with a lower risk than higher dose. Several NSAIDs had far higher than average risk including ketorolac 14.54 (95% CI, 5.87 to 36.04) and piroxicam 9.94 (95% CI, 5.99 to 16.50). The risks for celecoxib 1.42 (95% CI, 0.85 to 2.37) and ibuprofen 2.69 (95% CI, 2.17 to 3.33) were lower than NSAIDs overall. Relative risk for other commonly used NSAIDs including naproxen, indomethacin, meloxicam,

and diclofenac ranged from 3.98 to 5.63. Drugs with a long half-life or slow-release formulation were associated with higher risk even accounting for dose.⁴¹ Profound and coincident inhibition of both COX-1 and COX-2 using whole blood assay, as seen for ketorolac, piroxicam, naproxen, ketoprofen, and indomethacin, was associated with a relative risk of greater than 5 for GI bleeding and perforation.⁴¹ The use of low-dose aspirin, even in the absence of other risk factors, increases risk for bleeding and death. Many patients taking low-dose aspirin may do so without the knowledge of their physician; it is essential to query patients specifically on this point.

Other patient-specific factors influence the overall risk for GI ulcers and ulcer complications (Figure 59-5).^{45,77} A previous history of ulcer or ulcer complications is an important risk, especially if combined with other risks. Infection with *H. pylori* is likely to be associated with additive effect.⁷¹ It remains unclear if eradication of *H. pylori* would be useful in primary prevention of NSAID-induced ulcers, but this may be advantageous in those patients requiring long-term NSAIDs.⁴⁵ Eradication alone is insufficient as a single strategy for secondary prevention of ulcer complications. This strategy appears to be most effective in reducing the bleeding risk of patients on low-dose aspirin but is less useful than use of PPIs in patients taking NSAIDs.⁴⁵

Table 59-3 provides recommendations for patients who need NSAIDs and have GI risks.⁴⁵ Misoprostol has consistently been shown to be effective in reduction of gastroduodenal ulcers. Meta-analysis showed a reduction of 74% in gastric ulcers and 53% in duodenal ulcers when compared with placebo.⁷⁸ The effectiveness of misoprostol is comparable with the PPI lansoprazole.⁷⁹ However, the high prevalence of abdominal cramping and diarrhea limit misoprostol use at full doses. For those who do not tolerate full doses (200 mcg four times daily), lower doses of 400 to 600 mcg/day may be useful and comparable with PPIs.

PPIs have been used extensively for prevention of NSAID-induced ulcers and are also used for ulcer healing. Their excellent tolerability and availability over-the-counter have led to their dominance as pharmacologic agents for preventing NSAID-induced gastroduodenal ulcers. Studies have shown a reduction in endoscopic ulcer rate from 17% in patients taking traditional or COX-2-selective NSAIDs plus placebo to 5.2% and 4.6% in patients taking NSAIDs plus esomeprazole 20 mg or 40 mg, respectively.⁸⁰ As noted previously, a combination pill containing naproxen and

Table 59-3 Strategies for Gastrointestinal Risk Reduction⁴⁵

Gastrointestinal Risk	Potential Strategies
Low risk	Intermittent NSAID use Low-dose NSAID
Moderate risk (1-2 risk factors)	Intermittent NSAID use NSAID + PPI
Age > 65	NSAID + misoprostol
High-dose NSAID	NSAID + high-dose H ₂ RA*
Previous history of uncomplicated ulcer	
Concurrent use of aspirin, corticosteroids, or anticoagulants	
High risk	Alternative treatment
>2 Risk factors	COX-2-selective NSAID + PPI
History of previous complicated ulcer, especially recent	COX-2-selective NSAID + misoprostol
<i>Helicobacter pylori</i> positive	Consider eradication in moderate- to high-risk patients

*Less effective than PPI or misoprostol.

COX-2, cyclooxygenase-2; H₂RA, histamine-2-receptor antagonist; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitor.

esomeprazole has been approved for use. It may reduce non-compliance but will be associated with higher cost.

High-dose, twice-daily doses of H₂RA reduce the risk of NSAID-induced endoscopic ulcers and are the least costly alternative. However, these agents are inferior to PPIs and, like PPIs, there are no randomized clinical outcome trials that evaluate the efficacy of H₂RAs in chronic NSAID users.²⁴

Esophageal Injury

Aspirin and NSAIDs are associated with esophagitis related to mechanisms similar to those in the gastric mucosa.^{81,82} Esophageal emptying may be slowed in the elderly, resulting in a prolonged exposure of the mucosa to the irritant action of aspirin and NSAIDs. Gastroesophageal reflux may be an aggravating factor and lead to stricture formation. Bleeding may also complicate esophagitis. NSAIDs should be prescribed with caution in the presence of gastroesophageal reflux disease.

Small Bowel Injury

The availability of video capsule endoscopy (VCE) and balloon enteroscopy has advanced the ability to detect small intestinal lesions in patients taking NSAIDs. NSAIDs can cause a concentric “diaphragm-like” stricture in the small bowel in addition to causing mucosal injury and bleeding. Two recent studies of patients on NSAIDs for at least 3 months using VCE demonstrated a prevalence of 70% to 80% for small bowel injuries.⁸³ Furthermore, NSAID-induced small bowel injury is likely a common cause of obscure GI bleeding. NSAIDs that undergo enterohepatic circulation are likely to be associated with higher risk. Small bowel injury may be detected by anemia or symptoms of obstruction related to stricture.⁸³ Strategies effective for gastroduodenal ulcers such as misoprostol or certain PPIs may also reduce the risk for small bowel mucosal injury. Strictures may require balloon endoscopy or surgical intervention.⁸³

Colitis

NSAIDs cause erosions, ulcers, hemorrhage, perforations, strictures, and complications of diverticulosis in the large bowel.⁸⁴ NSAID-induced injury is more common in the right colon (80%) but can occur in the transverse and left colon. NSAID-containing suppositories can cause erosions, ulcers, and stenoses in the rectum. NSAID colonopathy is in the differential diagnosis of inflammatory bowel disease. Patients with NSAID-induced colonopathy are typically older, and the erosions are more likely to be transverse or circular.⁸⁵ There is also a concern that treatment with traditional and COX-2-selective NSAIDs may exacerbate inflammatory bowel disease.⁸⁶ NSAIDs are also implicated in the development of collagenous colitis.⁸⁷

Renal Effects

PGs play a vital role in solute and renovascular homeostasis.⁸⁸ It is becoming quite clear that PGs are produced by both COX-1 and COX-2, generally in different locations within the kidney, and that these PGs may play different physiologic roles in renal function.^{89,90} COX-1 is highly expressed in the renal vasculature, glomerular mesangial cells, and collecting duct. COX-2 expression is restricted to the vasculature, cortical thick ascending limb (specifically in cells associated with the macula densa), and in medullary interstitial cells. COX-2 expression in the macula densa increases in high-renin states (e.g., salt restriction, angiotensin-converting enzyme inhibition, renovascular hypertension), and selective COX-2 inhibitors significantly decrease plasma renin levels and renal renin activity. COX-2 expression in the macula densa is reduced by angiotensin II and mineralocorticoids. Dehydration or hypertonicity appears to regulate COX-2 expression in the medullary interstitium. COX-2 is also necessary for normal renal development.

Sodium Excretion

PGs are known to regulate renal sodium resorption by their ability to inhibit active transport of sodium in both the thick ascending limb and the collecting duct and to increase renal water excretion by blunting the actions of vasopressin.⁹¹ The cellular source of COX-2-derived prostanoids that promote natriuresis remains uncertain, but it is possible that they may in large part be derived from the medullary interstitial cells. Sodium retention has been reported to occur in up to 25% of NSAID-treated patients and may be particularly apparent in patients who have an existing avidity for sodium, such as those with mild heart failure or liver disease.⁹¹ Decreased sodium excretion in NSAID-treated patients can lead to weight gain and peripheral edema. This effect may be sufficiently important to cause clinically important exacerbations of congestive heart failure.

Hypertension

NSAIDs may cause altered blood pressure, with average increases of mean arterial pressure of between 5 and 10 mm Hg. In addition, using NSAIDs may increase the risk of

initiating antihypertensive therapy in older patients, with the magnitude of increased risk being proportional to the NSAID dose.⁹² Furthermore, in a large ($n = 51,630$) prospective cohort of women aged 44 to 69 without hypertension in 1990, incident hypertension over the following 8 years was significantly more likely in frequent users of aspirin, acetaminophen, and NSAIDs.⁹³ NSAIDs can attenuate the effects of antihypertensive agents including diuretics, angiotensin-converting enzyme inhibitors, and β -blockers, interfering with blood pressure control.

PGs stimulate renin release which, in turn, increases secretion of aldosterone and, subsequently, potassium secretion by the distal nephron. For this reason, NSAID-treated patients may develop hyporeninemic hypoaldosteronism that manifests as type IV renal tubular acidosis and hyperkalemia.⁹¹ The degree of hyperkalemia is generally mild; however, patients with renal insufficiency or those that may otherwise be prone to hyperkalemia (e.g., patients with diabetes mellitus and those on angiotensin-converting enzyme inhibitors or potassium-sparing diuretics) may be at greater risk.

Acute Renal Failure and Papillary Necrosis

Acute renal failure is an uncommon consequence of NSAID treatment. This is due to the vasoconstrictive effects of NSAIDs and is reversible. In most cases, renal failure occurs in patients who have a depleted actual or effective intravascular volume (e.g., congestive heart failure, cirrhosis, renal insufficiency).⁹¹

Marked reduction in medullary blood flow may result in papillary necrosis that may arise from apoptosis of medullary interstitial cells. Inhibition of COX-2 may be a predisposing factor.^{90,94}

Interstitial Nephritis

Another adverse renal effect resulting from NSAIDs involves an idiosyncratic reaction accompanied by massive proteinuria and acute interstitial nephritis. Hypersensitivity phenomena such as fever, rash, and eosinophilia may occur. This syndrome has been observed with most NSAIDs.

Chronic Kidney Disease

Use of analgesics, particularly acetaminophen and aspirin, has been associated with nephropathy leading to chronic renal failure. In one large case-control study, the regular use of aspirin or acetaminophen was associated with a risk of chronic renal failure 2.5 times as high as that for nonuse, and the risk increased significantly with an increasing cumulative lifetime dose.⁹⁵ In subjects regularly using both acetaminophen and aspirin, the risk was also significantly increased compared with users of either agent alone. No association between the use of nonaspirin NSAIDs and chronic renal failure could be detected after adjusting for acetaminophen and aspirin use. Pre-existing renal or systemic disease was a necessary precursor to analgesic-associated renal failure and those without pre-existing renal disease had only a small risk of end-stage renal disease.^{95,96}

Cardiovascular Effects

The risk of adverse cardiovascular effects associated with NSAID use was not widely appreciated until COX-2-selective NSAIDs were introduced into clinical practice. Rofecoxib, a potent, highly specific COX-2 inhibitor with a long half-life, was shown to have a substantially increased risk of MI and stroke and removed from the market because of this adverse effect.^{7,67} The mechanisms for cardiovascular risks associated with all NSAIDs are likely related to an imbalance between complete inhibition of COX-1 and COX-2 across the dosing interval. The COX-1 isoform is responsible for generation of platelet TXA₂, which facilitates platelet aggregation and thrombus formation. In order to inhibit this activity, COX-1 must be inhibited by 95% or greater.⁹⁷ Antithrombotic PGI₂ synthesized by endothelial COX-2 is inhibited almost completely by both traditional and COX-2-selective NSAIDs. It is proposed that the relationship between excess cardiovascular risk for all NSAIDs, not only COX-2-selective NSAIDs, is related to the degree of COX-2 inhibition absent complete inhibition of COX-1.⁹⁸ Investigators have shown that drugs that inhibit COX-2 less than 90% at therapeutic concentrations in the whole blood assay present a relative risk for MI of 1.18 (95% CI, 1.02 to 1.38), whereas drugs that inhibit COX-2 to a greater degree present a relative risk of 1.60 (95% CI, 1.41 to 1.81).⁹⁸

Relative inhibition of the COX isoforms is not the only mechanism that contributes to cardiovascular hazard. Other actions of NSAIDs including effects on blood pressure, endothelial function and nitric oxide production, and other renal effects may play a role in cardiovascular risks.^{67,99,100} Multiple analyses have demonstrated that the risk for cardiovascular hazard is significantly higher in those with pre-existing coronary artery disease. Some NSAIDs, notably ibuprofen and naproxen, may interfere with the irreversible inhibition of platelet COX-1 by aspirin, thereby increasing cardiovascular hazard in aspirin users.⁹⁸

A number of large-scale randomized controlled trials comparing NSAIDs with placebo or with each other have been performed and analyzed to determine the risk of MI, stroke, cardiovascular death, death from any cause, and Antiplatelet Trialists' Collaboration (APTC) composite outcomes.⁶⁷ Because event rates in most of these studies were low, uncertainty regarding absolute and relative risk remains. For example, there were only 554 MIs in aggregate across all trials included in the most comprehensive analysis to date. Nevertheless, it appears from analyses of these aggregated clinical trials that all traditional and COX-2-selective NSAIDs except naproxen carry an excess risk of more than 30% compared with placebo.⁶⁷ Pairwise comparisons of the most commonly used traditional and COX-2-selective NSAIDs studied in clinical trials also suggest that naproxen may have lower cardiovascular risk.⁶⁷ One meta-analysis explored the effects of dose and dosing regimen in a pooled analysis of six randomized placebo-controlled trials of celecoxib.¹⁰¹ Lower doses and once-daily regimens were associated with lower relative risks for the APTC outcomes. This finding confirms data from other studies that suggest avoiding continuous interference with PG biosynthesis is associated with lower cardiovascular risk.⁹⁸

Table 59-4 Strategies for Reducing Cardiovascular Risk^{67,98,102}

If using aspirin, take aspirin dose ≥ 2 hr before NSAID dose*
Do not use NSAIDs within 3-6 mo of an acute cardiovascular event or procedure
Carefully monitor and control blood pressure
Use low-dose, short half-life NSAIDs and avoid extended-release formulations

*Especially ibuprofen. Celecoxib does not appear to interfere with aspirin actions.

NSAID, nonsteroidal anti-inflammatory drug.

Because clinical trials have been underpowered to specifically address the relative cardiovascular risk of NSAIDs, investigators have turned to observational datasets. Using a large observational database with 8852 cases of nonfatal MI, a recent case-control study also identified a 35% increase in the risk of MI while using NSAIDs.⁹⁸ This type of study also identifies naproxen as potentially having a lower risk. In this analysis, long half-life was an independent predictor of MI hazard. The effect of dose and slow-release formulation demonstrated that risk was a direct consequence of prolonged drug exposure. It appears that the risk associated with these pharmacologic factors may be even more important than COX-2 specificity for most NSAIDs.^{67,98}

A number of strategies have been suggested to mitigate cardiovascular risks associated with NSAID use (Table 59-4).¹⁰² These recommendations take into account a patient's underlying risk, aspirin use, and the interaction between NSAIDs. In addition, the specific choice of NSAID should consider its pharmacologic properties.^{67,98}

Heart Failure

NSAIDs are associated with reduced sodium excretion, volume expansion, increased preload, and hypertension. As a result of these properties, patients with pre-existing heart failure are at risk of decompensation with a relative risk of 3.8 (95% CI, 1.1 to 12.7). After adjusting for age, sex, and concomitant medication, the relative risk was 9.9 (95% CI, 1.7 to 57.0).¹⁰³ Studies disagree as to whether NSAIDs are a risk for new heart failure, although the elderly may be at particular risk.^{103,104}

Closure of the Ductus Arteriosus

The maintenance of an open ductus arteriosus and its closure during the postnatal period are regulated by PG. COX-1, COX-2, and EP₄-deficient mice die from neonatal circulatory failure because the ductus arteriosus remains open. It is inadvisable for pregnant women to take NSAIDs during the last trimester of pregnancy because of the risk of a persistently patent ductus arteriosus.

Hepatic Effects

Small elevations of one or more liver tests may occur in up to 15% of patients taking NSAIDs, and notable elevations of alanine aminotransferase or aspartate aminotransferase (\approx three or more times the upper limit of normal) have been reported in approximately 1% of patients in clinical trials of NSAIDs. Patients usually have no symptoms, and discontinuation or dose reduction generally results in

normalization of the transaminase values, although rare, fatal outcomes have been reported with almost all NSAIDs. Those NSAIDs that appear most likely to be associated with hepatic adverse events are diclofenac and sulindac.

In clinical trial reports to the FDA, 5.4% of patients with rheumatoid arthritis who were treated with aspirin experienced persistent elevations of results in more than one liver function test. In children with viral illnesses, hepatocellular failure and fatty degeneration (Reye's syndrome) are associated with aspirin ingestion.⁵⁶

Asthma and Allergic Reactions

Asthma

Up to 10% to 20% of the general asthmatic population, especially those with the triad of vasomotor rhinitis, nasal polyposis, and asthma, are hypersensitive to aspirin. In these patients, ingestion of aspirin and nonspecific NSAIDs leads to severe exacerbations of asthma with naso-ocular reactions. Formerly termed aspirin-sensitive asthma, these patients are now characterized as having aspirin-exacerbated respiratory disease (AERD) because they have chronic upper and lower respiratory mucosal inflammation, sinusitis, nasal polyposis, and asthma independent of their hypersensitivity reactions. It is now thought that production of protective PGs in the setting of AERD is derived from a COX-1. A number of studies have been reported demonstrating that the COX-2-specific NSAIDs, rofecoxib and celecoxib, fail to trigger asthma exacerbation or naso-ocular symptoms in patients with AERD.^{105,106} Nevertheless, these studies were performed as challenge tests rather than long-term placebo-controlled trials, and caution is advised. The fact that specific COX-2 inhibitors appear safe in AERD does not imply that other hypersensitivity reactions do not occur.

Allergic Reactions

A wide variety of cutaneous reactions have been associated with NSAIDs. Almost all the NSAIDs have been associated with cutaneous vasculitis, erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. NSAIDs are also associated with urticaria/angioedema and anaphylactoid or anaphylactic reactions. Special note should be made that celecoxib and valdecoxib contain a sulfonamide group and should not be given to patients who report allergy to sulfa-containing drugs.

Hematologic Effects

Aplastic anemia, agranulocytosis, and thrombocytopenia are rarely associated with NSAIDs, but they are prominent among the causes of deaths attributed to these drugs. Because of the risk of hematologic effects, phenylbutazone is no longer recommended for use in any condition in the United States and has been taken off the market.¹⁰⁷

Effects on the Immune System

Virtually all cell types composing the immune system produce and respond to PGs. PGE₂ is a potent inhibitor of

chemotaxis, aggregation, superoxide production, lysosomal enzyme release, and LTB₄ generation of activated neutrophils.¹⁰⁸ Antigen-presenting cells play a pivotal role in the immune response, bridging local innate immune responses and the developing acquired immune response, which takes place in more specialized lymphoid organs. Bone marrow cultured in the presence of indomethacin yields increased numbers of dendritic cells, whereas bone marrow cultured in the presence of exogenous PGE₂ yields lower numbers of dendritic cells.¹⁰⁹ Dendritic cell cytokines are one of the many important factors that polarize the T cell response toward T-helper (Th)1, Th2, or Th17 cytokine profiles. Failure of dendritic cell maturation and/or their secretion of inhibitory cytokines leads to development of T regulatory cells that modulate T helper activity and suppress some of their functions.¹¹⁰ Eicosanoids are likely to be one of the tissue factors that determine dendritic cell phenotype during interaction with specific antigens/pathogens via pattern recognition receptors.¹¹⁰ Exogenous PGE₂ was reported to induce IL-23 production, important for generation of Th17 cells.^{111,112} A recent study using human peripheral blood mononuclear cells also supports a role for PGE₂ in promoting a Th17 response.¹¹³ Although a Th17 immune response is associated with development of autoimmune diseases, the clinical relevance of these observations with respect to NSAID use remains unclear.

PGE₂ also plays a role in B and T lymphocytes. PGE₂, through increased cAMP, inhibits many T cell functions.¹¹⁴ Treatment with COX-2-selective NSAIDs severely diminishes proliferation and expression of IL-2, TNF, and IFN- γ . B lymphocytes express COX-2 and produce PGE₂.¹¹⁵ Treatment with traditional and COX-2-selective NSAIDs profoundly reduced production of IgG and IgM after stimulation with minimal effects on proliferation. COX-2 null mice had 64% less IgM and 35% less IgG than normal littermates following *in vitro* treatment with LPS. COX-2-deficient mice also produce markedly reduced IgG and 10-fold reduced neutralizing antibody to HPV-like particles compared with WT mice without evidence of differences in B cell precursors.¹¹⁶ Similar findings of deficient humoral immune responses have been demonstrated for mice deficient in mPGES-1.¹¹⁷ Human memory B cell antibody production was also diminished in the presence of a specific COX-2 inhibitor.¹¹⁶ Again, the clinical relevance of these observations remains unclear with respect to NSAID use.

Central Nervous System Effects

Elderly patients may be particularly susceptible to developing cognitive dysfunction and other CNS effects including headache, dizziness, depression, hallucination, and seizures related to NSAIDs. Acute aseptic meningitis has been reported in patients with SLE or mixed connective tissue disease treated with ibuprofen, sulindac, tolmetin, or naproxen.

Effects on Bone

The complex effects of prostanoids on bone formation and remodeling have been appreciated for many years. It is now clear that COX-2 is required for many functions of both osteoblasts and osteoclasts.²⁷ COX-2 is rapidly inducible

and highly expressed and regulated in osteoblasts. Parathyroid hormone (PTH) is a strong inducer of COX-2. The production of PG by osteoblasts is an important mechanism for the regulation of bone turnover.²⁷ The major effect of PGE₂ is considered to occur indirectly via upregulation of receptor activator of NF κ B ligand (RANKL) expression and by inhibition of osteoprotegerin (OPG) expression in osteoblastic cells, which facilitated osteoclastogenesis. Genetic deletion of PTGS2 or COX-2-selective NSAIDs partially block the PTH- or 1,25-OH vitamin D-induced formation of osteoclasts in organ cultures. Recently, a familial disorder, primary idiopathic hypertrophic osteoarthropathy, was found to be associated with a mutation in the enzyme 15-hydroxyprostaglandin dehydrogenase, the enzyme that inactivates PGE₂.¹¹⁸ These patients have chronically elevated PGE₂ levels and digital clubbing with evidence of increased bone formation and resorption in the phalanges.

The role of endogenous PG and NSAIDs in skeletal pathology remains complex. LPS-induced bone loss can be ameliorated in mice lacking mPGES-1.¹¹⁹ Inflammatory bone loss likely reflects increased bone resorption and decreased bone formation.²⁷ It has long been appreciated that NSAIDs can inhibit experimental fracture healing and reduce formation of heterotopic bone in patients.¹²⁰ Furthermore, fracture healing is impaired in rats treated with specific COX-2 inhibitors and in mice with genetic deletion of the COX-2 gene.¹²¹ Given the effectiveness of NSAIDs as analgesics, it is important to understand the clinical concern regarding impaired fracture healing and NSAIDs. A recent meta-analysis found a pooled odds ratio for nonunion with NSAID exposure of 3 (95% CI, 1.6 to 5.6).¹²² However, there was a significant association between lower-quality studies, and higher reported odds ratios for nonunion was observed. When only higher-quality studies were considered, no statistically significant association between NSAID exposure and nonunion was identified.

The impact of NSAIDs on bone mineral density (BMD) also remains unclear.²⁷ In older men, daily use of COX-2-selective NSAIDs was associated with lower hip and spine BMD compared with nonusers, but in postmenopausal women not taking hormone replacement therapy there was a higher BMD.¹²³ It is speculated that the beneficial effects of mechanical loading may be reduced by COX-2 inhibition but that the proinflammatory state and increased bone turnover associated with estrogen withdrawal may be suppressed by COX-2 inhibition. Still, a causal role for endogenous PGs in bone loss resulting from estrogen deficiency has not been confirmed.

Effects on Ovarian and Uterine Function

PGs derived from COX-2 have been implicated as mediators in multiple stages of the female reproductive cycle. Induction of COX-2 immediately after the luteinizing hormone surge was the first observation involving the isoenzyme during a normal physiologic event. It has been suggested that COX-2-derived PGs may signal the time of ovulation in mammals.^{124,125} Studies using COX-2 null mice show reproductive failure at ovulation, fertilization, implantation, and decidualization.¹²⁶ COX-2-dependent prostanoid production probably leads to the generation of

proteolytic enzymes that rupture the follicles. After fertilization, COX-2 also plays a role in embryo implantation in the myometrium.¹²⁶ PGs are important for inducing uterine contractions during labor. Murine studies have shown that the mechanism of uterine contraction involves fetal release of PGF_{2α}, a compound that induces luteolysis. This pathway leads to reduced maternal progesterone levels, induction of oxytocin receptors in the myometrium, and parturition.

Based on these observations in animals, one could hypothesize that NSAIDs may have an influence on fertility. In fact, studies suggest that luteinized unruptured follicle syndrome as a cause of reversible infertility can be related to ingestion of NSAIDs.¹²⁷ For this reason, although it remains unproved in controlled or observational studies, women should be cautioned that chronic NSAID use may impair fertility.

Salicylate Intoxication and NSAID Overdose

The new appearance of tachypnea, confusion, ataxia, oliguria, or a rising blood urea nitrogen (BUN)/creatinine in a patient, particularly an elderly patient, taking aspirin or salicylates should suggest the possibility of salicylate intoxication. In adults, metabolic acidosis is masked by hyperventilation due to stimulation of respiratory centers, which is a direct effect of salicylates. Sudden increases in salicylate levels can occur even if there is no change in dose. This is particularly common in patients who develop acidosis from any cause, suffer from dehydration, or ingest other drugs that displace salicylate from protein-binding sites. Therapy consists of removing residual drug from the GI tract, forced diuresis while maintaining the urinary pH in the alkaline range and with potassium replacement, or hemodialysis if diuresis is unsatisfactory. Vitamin K is recommended because large doses of salicylate may interfere with the synthesis of the vitamin K-dependent clotting factors.

Acute overdoses of NSAIDs are much less toxic than are overdoses of aspirin or salicylates. This subject has been most carefully evaluated for ibuprofen, prompted by its approval for over-the-counter sale to the general public. Symptoms with overdoses ranging up to 40 g include CNS depression, seizures, apnea, nystagmus, blurred vision, diplopia, headache, tinnitus, bradycardia, hypotension, abdominal pain, nausea, vomiting, hematuria, abnormal renal function, coma, and cardiac arrest. Treatment includes prompt evacuation of the stomach contents, observation, and administration of fluids.

Adverse Effects of Acetaminophen

Acetaminophen is used widely as the first-line treatment of pain, chiefly because it is viewed as effective and safer than NSAIDs. Used in doses below 2 g daily, there is little evidence of toxicity.¹²⁸ Acetaminophen-induced acute liver failure is due to direct injury from the toxic metabolite, N-acetyl-*p*-benzoquinoneimine, a highly reactive electrophilic compound that depleted glutathione and subsequently accumulated in hepatocytes.¹²⁹ Acetaminophen is a highly predictable hepatotoxin with a threshold dose of 10 to 15 g in adults and 150 mg/kg in children. In the United States, acetaminophen overdoses are usually unintentional, with most taking acetaminophen preparations for

chronic pain. Intentional self-poisoning with acetaminophen also remains an important problem. Treatment of acetaminophen overdose includes gastric lavage, activated charcoal, or induction of vomiting within the first 3 hours of injection. In addition, intensive support measures and early treatment with *N*-acetylcysteine, which replenished glutathione, have reduced mortality associated with acute acetaminophen toxicity. With high doses of acetaminophen, other toxicities may occur including GI ulcers and bleeding.^{130,131} Regular use of acetaminophen has also been associated with an increased risk for chronic renal failure.⁹⁵

EFFECTS OF CONCOMITANT DRUGS, DISEASES, AND AGING

Because of the widespread use of prescription and nonprescription NSAIDs, there are ample opportunities for interaction with other drugs and for interactions with patient-specific factors.¹³² Specific drug interactions are listed on the package inserts of individual agents.

Drug-Drug Interactions

Because most NSAIDs are extensively bound to plasma proteins, they may displace other drugs from binding sites or may themselves be displaced by other agents. Aspirin and other NSAIDs may increase the activity or toxicity of sulfonylurea, hypoglycemic agents, oral anticoagulants, phenytoin, sulfonamides, and methotrexate by displacing these drugs from their protein-binding sites and increasing the free fraction of the drug in plasma.¹³² NSAIDs may blunt the antihypertensive effects of β -blockers, angiotensin-converting enzyme inhibitors, and thiazides leading to destabilization of blood pressure control.¹³³ There is an increased risk of GI toxicity when NSAIDs and selective serotonin reuptake inhibitors are taken concomitantly compared with taking either agent alone and more than an additive risk.¹³⁴

There are interactions between aspirin and NSAIDs, particularly ibuprofen, related to blocking the ability of aspirin to access the COX active site. This may be important when aspirin is used for prevention of cardiovascular disease. It is prudent to recommend that aspirin be taken 2 hours before ibuprofen dosing.^{102,135}

Drug-Disease Interactions

Rheumatoid arthritis and other diseases (e.g., hepatic and renal disease) that decrease serum albumin concentrations are associated with increased concentrations of free NSAIDs. Hepatic and renal diseases may also impair drug metabolism or excretion and thereby increase the toxicity of a given dose of NSAID to an individual patient. Renal insufficiency may be accompanied by accumulated endogenous organic acids that may displace NSAIDs from protein-binding sites.

Drug Reactions in the Elderly

Aging is accompanied by changes in physiology resulting in altered pharmacokinetics and pharmacodynamics. Decreased

drug clearance may be the consequence of reductions in hepatic mass, enzymatic activity, blood flow, renal plasma flow, glomerular filtration rate, and tubular function associated with aging. The elderly are more likely to experience adverse GI and renal effects related to NSAIDs. The increased risk of cardiovascular disease in elderly patients raises concerns of accelerated MI or stroke. The use of aspirin for prevention of cardiovascular disease increases the toxicity of NSAIDs, and conversely the concomitant use of NSAIDs may increase aspirin resistance. Use of PPI for gastroprotection may interfere with the efficacy of antiplatelet agents such as clopidogrel.¹³⁵ The elderly have more illnesses than younger patients and therefore take more medications, increasing the possibility of drug-drug interactions. Older patients may also be more likely to self-medicate or make errors in drug dosing. For these reasons, frequent monitoring for compliance and toxicity should be a part of the use of NSAIDs in this population.

COLCHICINE

Colchicine is frequently used in the context of NSAID replacement therapy when the latter are contraindicated. Colchicine exhibits excellent anti-inflammatory activity in acute gouty arthritis. A recent study has clarified that a low-dose colchicine regimen of 1.2 mg followed in 1 hour by 0.6 mg provides equal efficacy to higher-dose regimens with a marked reduction in adverse events.¹³⁶ Colchicine is also used to prevent acute gouty attacks. Prophylactic treatment appears to reduce the frequency of attacks by 75% to 85% and mitigates the severity of attacks that occur.¹³⁷ However, there is concern that prophylactic therapy should be initiated only if hyperuricemia is controlled because tophi may develop without the usual warning signs of acute gouty attacks. Albeit with less efficacy, colchicine treatment may also benefit patients with acute episodes of pseudogout and arthritis due to other crystals.

Daily colchicine (1.2 to 1.8 mg) is the mainstay of treatment for familial Mediterranean fever (FMF). It is effective in preventing acute attacks and amyloidosis. Colchicine has been used empirically in other rheumatologic disorders, where neutrophils play an important role such as Behçet's disease, recurring pericarditis, and cutaneous neutrophilic vasculitis.¹³⁸

Mechanism of Colchicine Action

Colchicine appears to interfere with steps of the inflammatory response in which neutrophils play a central role by interfering with the organization of the fibrillar microtubules involved in cell morphology and movement. This leads to disaggregation of microtubules and to decreased neutrophil motility and chemotaxis. Furthermore, colchicine inhibits release of chemotactic factors (e.g., leukotriene B₄), formation of digestive vacuoles, and lysosomal degranulation. This results in an inhibition of neutrophil migration into an area of inflammation and a reduction of the metabolic and phagocytic activity of the neutrophils already present. Clinically, this results in an interruption in the inflammatory process of gout and other neutrophil-dominated acute inflammatory diseases.¹³⁶

Adverse Effects of Colchicine

Because the mechanism of colchicine actions is different from NSAIDs, the adverse event profile is also different. More than 80% of patients who take a traditional high-dose oral therapeutic dose of colchicine for an acute gouty attack experience cramping, abdominal pain, diarrhea, nausea, or vomiting, and these symptoms usually limit the dose. For this reason, and because of equal efficacy, high-dose colchicine is not recommended for acute gout flare.¹³⁶

Bone marrow depression, hair loss, amenorrhea, dysmenorrhea, oligospermia, and azoospermia have been reported with chronic colchicine treatment.¹³⁸ There may be an increase in trisomy 21 in the offspring of FMF patients taking colchicine at the time of conception. Colchicine can cause subacute-onset muscle and peripheral nerve toxicity, particularly in patients with chronic renal failure. For this reason, colchicine should be used cautiously in patients with chronic renal failure and dose adjustment should be considered. Patients with colchicine-induced neuromyopathy present with proximal muscle weakness, elevated serum creatine kinase (CK) levels, and neuropathy and/or myopathy on electromyography (EMG).¹³⁹

Death has occurred with as little as 8 mg of colchicine but is inevitable after the ingestion of more than 40 mg. Treatment includes aspiration of the stomach, intensive support measures, and hemodialysis, although there is no specific evidence that colchicine can be removed by dialysis.

CHOOSING ANTI-INFLAMMATORY ANALGESIC THERAPY

In choosing an NSAID for a particular patient, the clinician must consider efficacy, potential toxicity related to concomitant drugs and patient factors, and cost. Furthermore, patient preference for factors such as dosing regimen may be taken into account. In addition to choices from the perspective of the individual patient and physician, it may be important to take a broader view. Choice of anti-inflammatory analgesic therapy can also be considered from the perspective of health care institutions and payers. The symptoms and conditions for which NSAIDs are used are extraordinarily common. Consequently, the cost of NSAIDs as a proportion of total drug costs can be high when drugs are expensive. The increased cost of branded NSAIDs has an important pharmacoeconomic impact. On the other hand, adverse events can have important economic consequences, and improved safety may be cost-effective.

Choosing anti-inflammatory analgesic therapy has become increasingly complex with the increased understanding of associated toxicities. Prospectively considering the presence of GI and cardiovascular risk factors is essential when considering treatment options (Table 59-5). GI risks are well known, and strategies to prevent ulceration and bleeding are available. Many questions regarding the risk for cardiovascular events in patients using NSAIDs exist. In general, the data suggest that physicians should be cautious in using NSAIDs in patients with known cardiovascular disease. In those patients with risks for

Table 59-5 Choosing Analgesic Anti-inflammatory Therapy

Risk Category	Treatment Recommendations
Low: <65 yr old No cardiovascular risk factors No requirement for high-dose or chronic therapy No concomitant aspirin, corticosteroids, or anticoagulants	Traditional NSAID Shortest duration and lowest dose possible
Intermediate: ≥65 yr old No history of previous complicated GI ulceration Low cardiovascular risk, may be using aspirin for primary prevention Requirement for chronic therapy and/or high-dose therapy	Traditional NSAID + PPI, misoprostol, or high-dose H ₂ RA Once-daily celecoxib + PPI, misoprostol, or high-dose H ₂ RA if taking aspirin If using aspirin, take low dose (75–81 mg) If using aspirin, take traditional NSAID ≥2 hr before aspirin dose
High: Elderly, especially if frail or if hypertension, renal, or liver disease present History of previous complicated ulcer or multiple GI risk factors History of cardiovascular disease and on aspirin or other antiplatelet agent for secondary prevention History of heart failure	Use acetaminophen <2 g/day Avoid chronic NSAIDs if at all possible: Use intermittent NSAID dosing Use low-dose, short half-life NSAIDs Do not use extended-release NSAID formulation If chronic NSAID required, consider: Once daily celecoxib + PPI/misoprostol (GI > CV risk) Naproxen + PPI/misoprostol (CV > GI risk) Avoid PPI if using antiplatelet agent such as clopidogrel Monitor and treat blood pressure Monitor creatinine and electrolytes

CV, cardiovascular; GI, gastrointestinal; H₂RA, histamine-2-receptor antagonist; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitor.

NSAID toxicity, avoiding potent drugs with a long half-life or extended-release formulations is prudent. Intermittent dosing rather than continuous daily use reduces toxicity.

Absence of anti-inflammatory activity reduces the effectiveness of acetaminophen for diseases accompanied by a significant component of inflammation (e.g., rheumatoid arthritis, gout). However, acetaminophen is a safe and effective alternative for milder pain conditions including osteoarthritis. With respect to patient preference, a survey study demonstrated that only 14% of a large group of rheumatic disease patients ($n = 1799$) with rheumatoid arthritis, osteoarthritis, or fibromyalgia preferred acetaminophen over NSAIDs, whereas 60% preferred NSAIDs.¹⁴⁰ In a head-to-head clinical trial of acetaminophen versus diclofenac plus misoprostol, there was significantly greater improvement in pain scores in patients in the diclofenac group. This finding was magnified in those patients with more severe disease at baseline.¹⁴¹

Acetaminophen should be tried as the initial therapy in patients with mild to moderate pain for reasons of safety and

cost. However, if patients have moderate to severe symptoms or if evidence of inflammation is present, moving to treatment with NSAIDs may provide more rapid and effective relief.¹⁴²

Future Directions

The strategy of blocking PG production by inhibiting the COX enzymes has provided relief from pain and inflammation for centuries. Given the proven importance of PG in this pathway and the advances in understanding the molecules involved, pharmacologic targeting of enzymes involved in biosynthesis, transport, or degradation may provide therapeutic efficacy. Similar to COX-2, mPGES-1 is induced during inflammation and in other pathologic states. Strategies to inhibit mPGES-1 have been proposed as potential alternatives to inhibiting COX.¹⁴³ Drug development has been somewhat hampered because of the species specificity of mPGES-1 binding. However, this may be a particularly appealing strategy because preclinical data suggest that inhibition of mPGES-1 is associated with a reduced propensity to develop hypertension, thrombosis, atherosclerotic plaques, aortic aneurysm, and neointimal hyperplasia after vascular injury.^{144–146} Additionally, receptor antagonists could also be useful. Indeed, a number of EP₄ receptor antagonists have proved useful in animal models of rheumatoid arthritis, osteoarthritis, and pain.¹⁸

Glucocorticoid Therapy

JOHANNES W.G. JACOBS •
JOHANNES W.J. BIJLSMA

KEY POINTS

Mode of action of glucocorticoids is genomic (via glucocorticoid receptor) and, in high dosages, also nongenomic.

Glucocorticoids differ considerably in potency and biologic half-life.

Cortisone and prednisone are biologically inactive and are converted in the liver into biologically active cortisol and prednisolone.

Glucocorticoids have disease-modifying properties in early rheumatoid arthritis.

The risk of adverse effects of a glucocorticoid is patient, dose, and time dependent.

The risk of adverse effects of low-dose glucocorticoids generally is overestimated.

After local injection of a glucocorticoid, the risk of local bacterial infection is very low.

Low and low-to-moderate doses of prednisolone in pregnancy appear to be safe.

Glucocorticoids are widely used for the treatment of patients with rheumatic disease. The first to be isolated, in 1935, was the naturally occurring glucocorticoid hormone, cortisone. It was synthesized in 1944 and subsequently became available for clinical use. In 1948, cortisone (then called *compound E*) was administered by the American physician Philip S. Hench to a 29-year-old woman with active rheumatoid arthritis (RA) of longer than 4 years' duration. Her joints were so painful she could "hardly get out of bed." After 2 days of treatment with 100 mg of intramuscular compound E daily, "She rolled over in bed with ease, and noted much less muscular soreness." The next day, she was able to walk with "only a slight limp." Hench published this case of dramatic improvement in 1949¹ and won the 1950 Nobel Prize in Physiology or Medicine for his research, which he shared with two colleagues at the Mayo Clinic. Later, by chemical modification of natural steroids, different synthetic glucocorticoids were produced, some of which have proved to be very effective anti-inflammatory and immunosuppressive substances with rapid, sometimes instant, effects.

Initially, there was considerable enthusiasm about glucocorticoid therapy because of the striking relief of symptoms seen in patients treated with supraphysiologic dosages. When the wide array of potentially serious adverse side

effects became apparent, however, the use of glucocorticoids decreased. Nevertheless, because glucocorticoids can be considered the most effective anti-inflammatory and immunosuppressive substances currently known, they have become a cornerstone of therapy for many rheumatic disorders, including systemic lupus erythematosus (SLE), vasculitis, polymyalgia rheumatica, and myositis. The use of glucocorticoids in therapeutic strategies for patients with RA has become accepted.

During past decades, knowledge about glucocorticoids has increased, but much remains to be learned about the modes of actions of these drugs in rheumatic autoimmune disorders. It is hoped that the unraveling of these mechanisms eventually may lead to new applications of glucocorticoids or novel classes of therapy.

CHARACTERISTICS OF GLUCOCORTICOIDS

Structure and Classification

The precursor molecule of all steroid hormones is cholesterol, which is also a building block for vitamin D and cell membranes and organelles (Figure 60-1). Steroid hormones and cholesterol are characterized by a sterol skeleton, formed by three six-carbon hexane rings and one five-carbon pentane ring. The carbon atoms of this sterol nucleus are numbered in a specific sequence; the term *steroid* refers to this basic sterol nucleus (Figure 60-2).

Steroid hormones can be classified on the basis of their main function into sex hormones (male and female), mineralocorticoids, and glucocorticoids. Sex hormones are synthesized mainly in the gonads, but also in the adrenal cortex. Mineralocorticoids and glucocorticoids are synthesized only in the adrenal cortex; the terms *corticosteroid* and *corticoid* for these hormones refer to the adrenal cortex. Some glucocorticoids also have a mineralocorticoid effect and vice versa. The main natural mineralocorticoid is aldosterone, and the main natural glucocorticoid is cortisol (hydrocortisone). Although separation of corticoids into the classes mineralocorticoids and glucocorticoids is not absolute (see later), it is better (more precise) to use the term *glucocorticoid* than the term *corticosteroid* when referring to one of these compounds.² The importance of standardized nomenclature is illustrated by the fact that an electronic literature search can be complicated by multiple synonyms.

In the 1950s, chemical modification of natural steroids revealed numerous structural features essential for specific biologic activities. Synthetic steroid hormones more potent than natural steroid hormones and steroid hormones with

Figure 60-1 Cholesterol as building block for steroid hormones, vitamin D, and cell membranes and organelles.

altered biologic activity were developed. This research showed that the 17-hydroxy, 21-carbon steroid configuration (see [Figure 60-2](#)) is required for glucocorticoid activity through binding to the glucocorticoid receptor. Glucocorticoids with an 11-keto, instead of an 11-hydroxy, group, such as cortisone and prednisone, are prohormones that must be reduced in the liver to their 11-hydroxy configurations. Cortisone is converted by hepatic pathways to cortisol, and prednisone is converted to prednisolone, to become biologically active. Thus in patients with severe liver disease, it is rational to prescribe prednisolone instead of prednisone.

The generation of biologically active glucocorticoids from their inactive forms is promoted by the reductase action of the intracellular enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) type 1. The same enzyme can by dehydrogenation promote the reverse reaction, leading to inactivation of active glucocorticoids. In contrast, 11 β -HSD type 2 has dehydrogenase activity only, so it catalyzes only the conversion of active glucocorticoids to their inactive forms. In different tissues, local balance between the intracellular enzymes 11 β -HSD type 1 and type 2 might modulate intracellular glucocorticoid concentrations and thus tissue sensitivity for glucocorticoids.³ Synovial tissue metabolizes glucocorticoids via the two 11 β -HSD enzymes, with the net effect being glucocorticoid activation; this increases with inflammation. This endogenous glucocorticoid production in the joint is likely to have an impact on local inflammation and on bone in the joint.⁴

No qualitative differences have been noted between the glucocorticoid effect of endogenous cortisol and that of exogenously applied synthetic glucocorticoids because these effects are, except for higher doses, predominantly genomic (i.e., mediated through the glucocorticoid receptor).⁵ However, quantitative differences have been identified. The potency and other biologic characteristics of glucocorticoids depend on structural differences in the steroid

configuration. The introduction of a double bond between the 1 and 2 positions of cortisol yields prednisolone, which has about four times more glucocorticoid activity than cortisol ([Table 60-1](#)).

Addition of a six-methyl group to prednisolone yields methylprednisolone, which is about five times more potent than cortisol. All the aforementioned glucocorticoids also have a mineralocorticoid effect. The synthetic glucocorticoids triamcinolone and dexamethasone have negligible mineralocorticoid activity, however.

Biologic Characteristics and Therapeutic Consequences

Apart from the steroid configuration, biologic characteristics of glucocorticoids also depend on whether they are in free form (as alcohol) or are chemically bound (as ester or salt). In their free form, glucocorticoids are virtually insoluble in water, so they can be used in tablets but not in parenteral preparations. For this reason, synthetic glucocorticoids are formulated as organic esters or as salts. Esters, such as (di)acetate and (hex)acetate, are lipid soluble but have limited water solubility and are suitable for oral use and intramuscular, intralesional, and intra-articular injection. Salts, such as sodium phosphate and sodium succinate, are generally more water soluble and thus are also suitable for intravenous use. Dexamethasone sodium phosphate can be used intravenously, whereas dexamethasone acetate cannot. When given intramuscularly, dexamethasone sodium phosphate is absorbed much faster from the injection site than dexamethasone acetate. If an immediate effect is required, dexamethasone sodium phosphate given intravenously is more rapidly effective than the same preparation given intramuscularly; the least rapidly active is that of intramuscular dexamethasone acetate. For local use, less solubility means longer duration of the local effect, which generally is beneficial.

Figure 60-2 Basic steroid configuration and structure of cholesterol and of natural and some synthetic glucocorticoids. Structural differences of glucocorticoids compared with cortisol, the natural active glucocorticoid, are shown in red.

Pharmacokinetics and Pharmacology

Water insolubility does not impair absorption from the digestive tract. Most orally administered glucocorticoids, whether in free form or as an ester or salt, are absorbed readily, probably within about 30 minutes. Bioavailability

of prednisone and prednisolone is high. Commercially available oral and rectal prednisone and prednisolone preparations are considered approximately bioequivalent.

The affinity of the different glucocorticoids for various plasma proteins varies (see Table 60-1). Of cortisol in plasma, 90% to 95% is bound to plasma proteins, primarily

Table 60-1 Pharmacodynamics of Commonly Used Glucocorticoids

	Equivalent Glucocorticoid Dose (mg)	Relative Glucocorticoid Activity	Relative Mineralocorticoid Activity*	Protein Binding	Plasma Half-Life	Biologic Half-Life (hr)
Short-Acting						
Cortisone	25	0.8	0.8	–	0.5	8-12
Cortisol	20	1	1	++++	1.5-2	8-12
Intermediate-Acting						
Methylprednisolone	4	5	0.5	–	>3.5	18-36
Prednisolone	5	4	0.6	++	2.1-3.5	18-36
Prednisone	5	4	0.6	+++	3.4-3.8	18-36
Triamcinolone	4	5	0	++	2->5	18-36
Long-Acting						
Dexamethasone	0.75	20-30	0	++	3-4.5	36-54
Betamethasone	0.6	20-30	0	++	3-5	36-54

*Clinically; sodium and water retention, potassium depletion.

transcortin (also called *corticosteroid-binding globulin*) and, to a lesser degree, albumin. Protein-bound cortisol is not biologically active, but the remaining 5% to 10% of free cortisol is. Prednisolone has—in contrast to methylprednisolone, dexamethasone, and triamcinolone—a high affinity for transcortin and competes with cortisol for this binding protein. The other synthetic glucocorticoids with little or no affinity for transcortin are two-thirds (weakly) bound to albumin, and about one-third circulate as free glucocorticoid.

Because only unbound glucocorticoids are pharmacologically active, patients with low levels of plasma protein, such as albumin (e.g., because of liver diseases or chronic active inflammatory diseases), are more susceptible to effects and side effects of glucocorticoids. Dosage adjustment should be considered in these patients. In liver disease, an additional argument for dosage adjustment is reduced clearance of glucocorticoids (see later).

Glucocorticoids have biologic half-lives 2 to 36 times longer than their plasma half-lives (see Table 60-1). With a plasma half-life of about 3 hours, prednisolone can be dosed once daily for most diseases. Maximal effects of glucocorticoids lag behind peak serum concentrations. Transcortin binds these compounds more strongly than does albumin. The plasma elimination of glucocorticoids bound to transcortin is slower than that of glucocorticoids that do not bind. Transcortin binding is not a major determinant of biologic half-lives of glucocorticoids, however, in contrast to distribution to different compartments of the body and binding to the cytosolic glucocorticoid receptor. Synthetic glucocorticoids have lower affinity for transcortin but higher affinity for the cytosolic glucocorticoid receptor than does cortisol (see later). The affinity of prednisolone and triamcinolone for the glucocorticoid receptor is approximately two times higher, and for dexamethasone it is seven times higher. Prednisone and cortisone have had negligible glucocorticoid bioactivity before they have been chemically reduced because of their very low affinity for the glucocorticoid receptor.

Another important factor determining biologic half-lives of glucocorticoids is the rate of metabolism. Synthetic glucocorticoids are subject to the same reduction, oxidation, hydroxylation, and conjugation reactions as cortisol.

Pharmacologically active glucocorticoids are metabolized primarily in the liver into inactive metabolites and are excreted by the kidneys; only small amounts of unmetabolized drug are also excreted in the urine. An inverse correlation has been noted between prednisolone clearance and age, which means that a given dose may have a greater effect in older individuals.⁶ Prednisolone clearance also is slower in African-Americans compared with that in whites.⁷ The serum half-life of prednisolone is 2.5 to 5 hours, but it is increased in patients with renal disease and liver cirrhosis, and in the elderly. Prednisolone can be removed by hemodialysis, but overall, the amount removed does not require dosage adjustment in patients on hemodialysis. In patients with cirrhosis of the liver, clearance of unbound steroid is about two-thirds of normal—a difference that should be taken into account with dosing.

Drug Interactions

Cytochrome P450 (CYP) is a family of isozymes responsible for the biotransformation of several drugs. Drug interactions can be based on induction or on inhibition of these enzymes. Certain drugs (e.g., barbiturates, phenytoin, rifampin) by inducing CYP isoenzymes (e.g., CYP3A4) increase the metabolism (breakdown) of synthetic and natural glucocorticoids, particularly by enhancing hepatic hydroxylase activity, thus reducing glucocorticoid concentrations (Figure 60-3). Rifampin-induced nonresponsiveness to prednisone in inflammatory diseases indeed has been described,^{8,9} as has rifampin-induced adrenal crisis in patients on glucocorticoid replacement therapy.¹⁰ Clinicians should consider increasing the dosage of glucocorticoids in patients who are concomitantly treated with these medications.

Conversely, concomitant use of glucocorticoids with inhibitors of CYP3A4 (e.g., ketoconazole, itraconazole, diltiazem, mibefradil and grapefruit juice) decreases glucocorticoid clearance and leads to higher concentrations and prolonged biologic half-lives of glucocorticoid drugs, thus increasing the risk of adverse effects.¹¹ Antifungal therapies, especially ketoconazole, on the other hand are known to interfere with endogenous glucocorticoid synthesis and therefore are also used, in doses of 400 to 800 mg per day, to treat hypercortisolism.¹¹ Etomidate, a

Figure 60-3 Serum prednisolone concentration in time in one patient, after 0.9 mg/kg prednisone orally daily, in the presence and absence of therapy with rifampin. Curve with rifampin, during a period of continuous administration of both drugs. Curve without rifampin, after a washout of rifampin of 4 weeks. Rifampin induces a reduced area under the curve of prednisolone, indicating reduced bioavailability.⁸

short-acting intravenous anesthetic agent used for the induction of general anesthesia and for sedation, can also lower cortisol levels, which could be clinically relevant in critically ill patients.¹¹

Concomitant administration of prednisolone and cyclosporine may result in increased plasma concentrations of the former drug; concomitant administration of methylprednisolone and cyclosporine may result in increased plasma concentrations of the latter drug. The mechanism of this probably is competitive inhibition of microsomal liver enzymes. Antibiotics such as erythromycin may increase plasma concentrations of glucocorticoids. Synthetic estrogens in oral contraceptives increase the level of transcortin and thus total (sum of bound and unbound) glucocorticoid levels. Therefore, in women taking oral contraceptives, care is required in the interpretation of cortisol measurements, especially because adrenal insufficiency may be present even when total cortisol levels are within the normal range.¹² Next to glucocorticoids, other steroid drugs such as megestrol acetate and medroxyprogesterone inhibit the hypothalamic-pituitary-adrenal axis¹¹; this risk may be increased when they are used concomitantly with glucocorticoids. Sulfasalazine has been reported to increase the sensitivity of immune cells for glucocorticoids,¹³ which could be beneficial.

Pregnancy and Lactation

In pregnancy, two mechanisms protect the fetus from exogenous glucocorticoids. First, glucocorticoids bound to transport proteins cannot pass the placenta, in contrast to unbound glucocorticoids. Second, the enzyme 11 β -HSD in the placenta, which catalyzes the conversion of active cortisol, corticosterone, and prednisolone into the inactive 11-dehydro-prohormones (cortisone, 11-dehydrocorticosterone, and prednisone), protects the fetus from glucocorticoids in the blood of the mother. The maternal-to-fetal prednisolone blood concentration ratio is about 10:1, owing to these mechanisms. In contrast, dexamethasone has little or no affinity for transport proteins and is poorly metabolized by 11 β -HSD in the placenta; the

maternal-to-fetal dexamethasone blood concentration ratio is about 1:1.

If a pregnant woman has to be treated with glucocorticoids, prednisone, prednisolone, and methylprednisolone would be good choices; if the unborn child has to be treated, fluorinated glucocorticoids, such as betamethasone or dexamethasone, would be indicated. Fear of physical (e.g., reduced growth) and neurocognitive adverse effects in children exposed to antenatal repeat doses of 12 mg betamethasone has not been substantiated,^{14,15} in contrast to postnatal glucocorticoid exposure.¹⁶ However, because of a small but increased risk of an oral cleft, it is advised to avoid high doses (1 to 2 mg/kg prednisone equivalent) in the first trimester of pregnancy,^{17,18} whereas low to moderate doses of prednisone seem to be safe.¹⁸

Prednisolone and prednisone are excreted in small quantities in breast milk. Breastfeeding is generally considered safe for an infant whose mother is taking these drugs. Because curves of milk and serum concentrations for prednisolone are virtually parallel in time, exposure of the infant is minimized if breastfeeding is avoided during the first 4 hours after the intake of prednisolone.¹⁸

BASIC MECHANISMS OF GLUCOCORTICIDS

Genomic and Nongenomic Effects

Glucocorticoids at any therapeutically relevant dosage exhibit pharmacologic effects via classic genomic mechanisms. The lipophilic glucocorticoid passes across the cell membrane, attaches to the cytosolic glucocorticoid receptor and heat shock protein, and binds to glucocorticoid-responsive elements on genomic DNA; it interacts with nuclear transcription factors. This process takes time. When acting through genomic mechanisms, it takes at least 30 minutes before the clinical effect of a glucocorticoid begins to show.¹⁹ Only when high doses are given, as in pulse therapy, can glucocorticoids act within minutes by nongenomic mechanisms; this occurs via specific receptor-mediated activity or via nonspecific membrane-associated physicochemical activity.⁵ The response to high-dose pulse methylprednisolone therapy may be biphasic, consisting of an early, rapid, nongenomic effect and a delayed and more sustained classic genomic effect.²⁰ Clinically, genomic and nongenomic effects cannot be separated, however.

Genomic Mechanisms

Most of the effects of glucocorticoids are exerted via genomic mechanisms by binding to the glucocorticoid receptor located in the cytoplasm of the target cells; glucocorticoids are lipophilic and have a low molecular mass; thus they can pass through the cell membrane easily. Next to the tissue-specific intracellular density of glucocorticoid receptors, the balance of intracellular 11 β -HSDs (see earlier) probably determines the sensitivity of specific tissues for glucocorticoids.³ Of the isoforms α and β of the glucocorticoid receptor, only the α isoform, common in all target tissues, binds to glucocorticoids.¹⁹ This is a 94-kD protein to which several heat shock proteins (chaperones) are bound. Binding of the glucocorticoid to this complex causes shedding of

the chaperones. The resulting activated glucocorticoid receptor–glucocorticoid complex is rapidly translocated into the nucleus, where it binds (as a dimer) to specific consensus sites in the DNA (glucocorticoid-responsive elements), regulating the transcription of a large variety of target genes. This process is termed *transactivation*. Binding to glucocorticoid-responsive elements results in stimulation or suppression of transcription of these target genes. Suppression of genes also may be mediated by mechanisms involving interaction of the glucocorticoid receptor–glucocorticoid complex (as a monomer) with transcriptional factors, such as activator protein-1 and nuclear factor κ B.²¹ This process is termed *transrepression* (Figure 60-4).

The nature and availability of these transcription factors may be pivotal in determining the differential sensitivity of different tissues to glucocorticoids because they play a crucial role in regulating the expression of a wide variety of proinflammatory genes induced by cytokines. The binding of transcriptional factors to DNA is inhibited by glucocorticoids, resulting in depressed expression of these genes and inhibition of their amplifying role in inflammation. Activated glucocorticoid receptors also may inhibit protein synthesis by decreasing the stability of mRNA through the induction of ribonucleases. This mechanism has been proposed to mediate glucocorticoid-induced inhibition of the synthesis of interleukin (IL)-1, IL-6, granulocyte-macrophage colony-stimulating factor, and inducible cyclooxygenase (COX)-2.²²

There is increasing acceptance of the hypothesis that side effects of glucocorticoids, such as diabetes mellitus, osteoporosis, skin atrophy, growth retardation, and cushingoid appearance, may be based predominantly on transactivation of genes after binding of glucocorticoid receptor–glucocorticoid to DNA, whereas the anti-inflammatory effects may be due mostly to the binding of a single glucocorticoid receptor–glucocorticoid complex to

transcription factors or co-activators, resulting in gene repression (transrepression). Understanding of these molecular mechanisms may lead to development of novel glucocorticoids, such as selective glucocorticoid receptor agonists, with a more favorable balance of transactivation and transrepression and, clinically, to a more favorable balance of metabolic and endocrine side effects and therapeutic effects²¹ (see later).

Expression of multiple target genes at the post-transcriptional level, also those influenced by glucocorticoids, is modulated by microRNAs (miRNAs), short noncoding RNA molecules that are implicated in a wide array of cellular and immune processes. Abnormal expression of miRNAs has been found in patients with rheumatoid arthritis. This identifies miRNAs as targets for immunomodulatory drug development.²³

Glucocorticoid Effects on the Immune System

Glucocorticoids reduce activation, proliferation, differentiation, and survival of a variety of inflammatory cells, including macrophages and T lymphocytes, and promote apoptosis, especially in immature and activated T cells (Figure 60-5). This activity is mediated mainly by changes in cytokine production and secretion. In contrast, B lymphocytes and neutrophils are less sensitive to glucocorticoids, and their survival may be increased by glucocorticoid treatment. The main effect of glucocorticoids on neutrophils seems to be inhibition of adhesion to endothelial cells. Glucocorticoids inhibit not only the expression of adhesion molecules, but also the secretion of complement pathway proteins and prostaglandins. At supraphysiologic concentrations, glucocorticoids suppress fibroblast proliferation and IL-1 and tumor necrosis factor (TNF)-induced metalloproteinase synthesis. By these effects, glucocorticoids may retard bone and cartilage destruction in the inflamed joint.²⁴

Figure 60-4 Genomic action of glucocorticoids. Glucocorticoid binds to the glucocorticoid receptor in the cytoplasm. This complex migrates into the nucleus. Activation of transcription (transactivation) by binding of glucocorticoid receptor–glucocorticoid dimers to glucocorticoid-responsive elements of DNA up-regulates synthesis of regulatory proteins, thought to be responsible for metabolic effects and also some anti-inflammatory/immunosuppressive effects. Interference of glucocorticoid receptor–glucocorticoid monomers with proinflammatory transcription factors, such as nuclear factor κ B (NF κ B), inhibits their binding to NF κ B-responsive elements of DNA and transcription. This is called *transrepression* and down-regulates synthesis of predominantly inflammatory/immunosuppressive proteins.

Figure 60-5 Effects shown in red type. Downregulation of adhesion molecules decreases migration of neutrophils and increases the number of circulating neutrophils. GC, glucocorticoid; IFN- γ , interferon- γ ; IL, interleukin; NK, natural killer; Tc, cytotoxic T lymphocyte; Th, helper T lymphocyte; TNF, tumor necrosis factor. (Modified from Sternberg E: Neural regulation of innate immunity: a coordinated nonspecific host response to pathogens, *Nat Rev Immunol* 6:318–328, 2006.)

Leukocytes and Fibroblasts

Administration of glucocorticoids leads to an increase in the total leukocyte count caused by an increase in circulating neutrophil granulocytes in the blood, although the numbers of other leukocyte subsets in blood such as eosinophil and basophil granulocytes, monocytes/macrophages (decreased myelopoiesis and bone marrow release), and T cells (redistribution effect) are decreased. Table 60-2 summarizes the effects of glucocorticoids on leukocyte subsets. The redistribution of lymphocytes, which is maximal 4 to 6 hours after administration of a single high dose of prednisone and returns to normal within 24 hours, has no clinical consequences. B cell function and immunoglobulin production are hardly affected. The effects of glucocorticoids on monocytes and macrophages, including decreased expression of major histocompatibility complex (MHC) class II molecules and Fc receptors, may increase susceptibility to infection, however.²⁵ Effects of glucocorticoids on fibroblasts include decreased proliferation and decreased production of fibronectin and prostaglandins.

Cytokines

The influence of glucocorticoids on cytokine production and action represents one of the major mechanisms of

glucocorticoid action in chronic inflammatory diseases such as RA. Glucocorticoids exert potent inhibitory effects on the transcription and action of a large variety of cytokines with pivotal importance in the pathogenesis of RA. Most T helper type 1 (Th1) proinflammatory cytokines are inhibited by glucocorticoids, including IL-1 β , IL-2, IL-3, IL-6,

Table 60-2 Anti-inflammatory Effects of Glucocorticoids on Immune Cells

Cell Type	Effects
Neutrophils	Increased blood count, decreased trafficking, relatively unaltered functioning
Macrophages and monocytes	Decreased blood count, decreased trafficking, decreased phagocytosis and bactericidal effects, inhibited antigen presentation, decreased cytokine and eicosanoid release
Lymphocytes	Decreased blood count, decreased trafficking, decreased cytokine production, decreased proliferation and impaired activation, little effect on immunoglobulin synthesis
Eosinophils	Decreased blood count, increased apoptosis
Basophils	Decreased blood count, decreased release of mediators of inflammation

TNF, interferon- γ (indicative of Th1 helper cells), IL-17 (indicative of Th17 helper cells), and granulocyte-macrophage colony-stimulating factor (see [Figure 60-5](#)). In RA, these cytokines are considered responsible for synovitis, cartilage degradation, and bone erosion. Conversely, the production of Th2 cytokines, such as IL-4, IL-10, and IL-13, may be stimulated or not affected by glucocorticoids (see [Figure 60-5](#)).²⁶ These cytokines have been related to the extra-articular features of erosive RA associated with B cell overactivity, such as immune complex formation and vasculitis. Activation of Th2 cells can suppress rheumatoid synovitis and joint destruction through release of the anti-inflammatory cytokines IL-4 and IL-10, which inhibit Th1 activity and downregulate monocyte and macrophage functions.²⁷

Inflammatory Enzymes

An important part of the inflammatory cascade is arachidonic acid metabolism, which leads to the production of prostaglandins and leukotrienes, most of which are strongly proinflammatory. Through the induction of lipocortin (an inhibitor of phospholipase A₂), glucocorticoids inhibit the formation of arachidonic acid metabolites. Glucocorticoids also have been shown to inhibit the production of COX-2 and phospholipase A₂ induced by cytokines in monocytes/macrophages, fibroblasts, and endothelial cells. In addition, glucocorticoids are potent inhibitors of the production of metalloproteinases *in vitro* and *in vivo*, especially collagenase and stromelysin, which are the main effectors of cartilage degradation induced by IL-1 and TNF.²⁸

Adhesion Molecules and Permeability Factors

Pharmacologic doses of glucocorticoids dramatically inhibit exudation of plasma and migration of leukocytes into inflammatory sites. Adhesion molecules play a central role in chronic inflammatory diseases by controlling the trafficking of inflammatory cells into sites of inflammation. Glucocorticoids reduce the expression of adhesion molecules through inhibition of proinflammatory cytokines and by direct inhibitory effects on the expression of adhesion molecules, such as intercellular adhesion molecule-1 and E-selectin.²⁹ Chemotactic cytokines attracting immune cells to the inflammatory site, such as IL-8 and macrophage chemoattractant proteins, also are inhibited by glucocorticoids. Nitric oxide production in inflammatory sites is increased by proinflammatory cytokines, resulting in increased blood flow, exudation, and probably amplification of the inflammatory response. The inducible form of nitric oxide synthase by cytokines is potently inhibited by glucocorticoids.³⁰

Hypothalamic-Pituitary-Adrenal Axis

Pathophysiology

Proinflammatory cytokines, such as IL-1 and IL-6, and eicosanoids, such as prostaglandin E₂, and endotoxins all activate corticotropin-releasing hormone (CRH) at the hypothalamic level ([Figure 60-6](#)). This activation stimulates the secretion of adrenocorticotrophic hormone (ACTH)

by the pituitary gland and of glucocorticoids by the adrenal glands. In otherwise healthy individuals with severe infection or other major physical stress, cortisol production may increase to six times the normal amount.¹² In patients with active RA (or other chronic inflammatory diseases), the increase in cortisol driven by elevated cytokines might be inappropriately low,³¹ meaning that cortisol levels—although normal or elevated in the absolute sense—are insufficient to control the inflammatory response. This is the concept of relative adrenal insufficiency.³¹⁻³³ Endogenous and exogenous glucocorticoids exert negative feedback control on the hypothalamic-pituitary-adrenal axis directly by suppressing secretion of ACTH and CRH, and indirectly by suppressing release from inflammatory tissues of proinflammatory cytokines, which stimulate secretion of ACTH and CRH (see [Figure 60-6](#)). Sensitivity of the hypothalamic-pituitary-adrenal axis for proinflammatory cytokines is probably decreased in RA.³⁴

ACTH is secreted in brief, episodic bursts, resulting in sharp increases in plasma concentrations of ACTH and cortisol, followed by slower declines in cortisol levels—the normal diurnal rhythm in cortisol secretion. Secretory ACTH episodic bursts increase in amplitude but not in frequency after 3 to 5 hours of sleep, reach a maximum during the hours before and the hour after awakening, decline throughout the morning, and are minimal in the evening. Cortisol levels are highest at about the time of awakening in the morning, are low in the late afternoon and evening, and reach their lowest level some hours after falling asleep (see [Figure 60-6](#)). Glucocorticoids are not stored in the adrenal glands in significant quantities. Continuing synthesis and release are required to maintain basal secretion or to increase blood levels during stress. The total daily basal or physiologic secretion of cortisol in humans has been estimated to range from 5.7 to 10 mg/m²/day.^{35,36} This would be covered in primary adrenal insufficiency by oral administration of 15 to 25 mg cortisol,³⁵ equivalent to about 4 to 6 mg prednisone. This low daily cortisol production rate may explain the cushingoid symptoms and other adverse effects that are sometimes observed in patients with adrenal insufficiency who are using glucocorticoids at doses previously regarded to be replacement doses (based on estimates of physiologic secretion of cortisol of 12 to 15 mg/m²/day), which are in fact supraphysiologic doses.

Effects of Glucocorticoids on the Hypothalamic-Pituitary-Adrenal Axis

Chronic suppression of the hypothalamic-pituitary-adrenal axis by administration of exogenous glucocorticoids leads by negative feedback loops on CRH and ACTH (see [Figure 60-6](#)) to failure in pituitary ACTH release, and thus to partial functional adrenal atrophy with loss of cortisol secretory capability in the fasciculata-reticularis zone. This inner cortical zone is the site of cortisol and adrenal androgen synthesis and is dependent on ACTH for structure and function. The outer cortical (glomerulosa) zone is involved in mineralocorticoid (aldosterone) biosynthesis and is functionally independent of ACTH. It stays functionally intact. Patients have failure of pituitary ACTH release and adrenal

Figure 60-6 Upper part, Stimulation (plus signs) and inhibition (minus signs) of the hypothalamic-hypopituitary-adrenal axis. Lower part, On the x-axis hours, plasma cortisol levels (blue line) in rheumatoid arthritis (RA) show an earlier and higher circadian rise compared with those in healthy controls, possibly caused by the rise in the proinflammatory cytokine interleukin-6 (IL-6); this rise is absent in healthy controls. IL-6 stimulates the hypothalamus and thus the release of cortisol, but probably also contributes to early morning stiffness and other inflammatory symptoms in (rheumatoid) arthritis. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

responsiveness to ACTH. Serum cortisol, ACTH levels, and adrenal responsiveness to ACTH are low, but other pituitary axes function normally, in contrast to the situation in most primary pituitary disorders. The time required to achieve suppression depends on the dosage and the serum half-life of the glucocorticoid used, but it also varies among patients, probably because of individual differences in glucocorticoid sensitivity and rates of glucocorticoid metabolism. Prediction with certainty of chronic suppression of the hypothalamic-pituitary-adrenal axis and adrenal insufficiency is impossible. This risk may be increased when glucocorticoids are used concomitantly with other steroid drugs such as megestrol acetate and medroxyprogesterone, inhibiting the hypothalamic-pituitary-adrenal axis.¹¹

The duration of the anti-inflammatory effect of one dose of a glucocorticoid approximates the duration of hypothalamic-pituitary-adrenal suppression. After a single oral dose of 250 mg of hydrocortisone or cortisone, 50 mg of prednisone or prednisolone, or 40 mg of methylprednisolone, suppression for 1.25 to 1.5 days has been described. Duration of suppression after 40 mg of triamcinolone and 5 mg of dexamethasone was 2.25 and 2.75 days.³⁷ After intramuscular administration of a single dose of 40 to 80 mg of triamcinolone acetonide, the duration of hypothalamic-pituitary-adrenal suppression is 2 to 4 weeks, and after 40 to 80 mg of methylprednisolone, suppression lasts 4 to 8 days.³⁷

In the case of long-term therapy, for patients who have had less than 10 mg of prednisone or its equivalent per day in one dose in the morning, the risk of clinical (symptomatic) adrenal insufficiency is not high, but neither is it negligible. A review of adrenal insufficiency stated that if the daily dose is 7.5 mg of prednisolone or equivalent or more for at least 3 weeks, adrenal hypofunction should be anticipated, and acute cessation of glucocorticoid in this situation could lead to problems.¹² Patients who have received glucocorticoids for less than 3 weeks or have been treated with alternate-day prednisolone therapy do not have zero risk of suppression of the hypothalamic-pituitary-adrenal axis, depending on the dose,^{38,39} but the risk is low. After 5 to 30 days of at least 25 mg of prednisone or equivalent daily, suppression of adrenal response (measured by a low-dose corticotropin test) was present in 34 of 75 patients studied (45%).⁴⁰ In these patients, a basal plasma cortisol concentration less than 100 nmol/L was highly suggestive of adrenal suppression, whereas levels of basal cortisol greater than 220 nmol/L predicted a normal adrenal response in most, but not all, patients. When in doubt, it seems prudent to treat patients as having secondary adrenal insufficiency. Secondary adrenal insufficiency generally has a less dramatic presentation than primary adrenal insufficiency because aldosterone levels, which are controlled predominantly by the renin-angiotensin system, are preserved; mineralocorticoid therapy is not necessary.

TREATMENT WITH GLUCOCORTICOIDS

Glucocorticoids are widely used in various dosages for several rheumatic diseases. Often it is unclear what is meant by the semi-quantitative terms used for dosages, such as *low*

Table 60-3 Terminology of Dosages of Glucocorticoids for Use in Rheumatology

Low dose	≤7.5 mg prednisone or equivalent per day
Medium dose	>7.5 mg, but ≤30 mg prednisone or equivalent per day
High dose	>30 mg, but ≤100 mg prednisone or equivalent per day
Very high dose	>100 mg prednisone or equivalent per day
Pulse therapy	≥250 mg prednisone or equivalent per day for 1 day or a few days

or *high*. Based on pathophysiologic and pharmacokinetic data, standardization has been proposed to minimize problems in interpretation of these generally used terms (Table 60-3).²

Indications

For each disease, indications for glucocorticoid therapy are discussed in the specific chapters. An overview is given here (Table 60-4), which summarizes only the general uses and dosages of glucocorticoids. Without detailed description, some of the indications could be considered questionable at first glance. In systemic sclerosis, glucocorticoids, especially in high doses, are contraindicated because of the risk of scleroderma renal crisis, but they may be useful for myositis or interstitial lung disease. Glucocorticoids are a basic part of the therapeutic strategy in myositis, polymyalgia rheumatica, and systemic vasculitis. For other diseases, glucocorticoids serve as adjunctive therapy or are not used at all. For instance in RA, glucocorticoids are almost exclusively used as adjunctive therapy in combination with other disease-modifying antirheumatic drugs (DMARDs) (see later). In osteoarthritis, glucocorticoids are not given except for intra-articular injection if signs of synovitis of the osteoarthritic joint are present.⁴¹ For generalized soft tissue disorders, glucocorticoids are not indicated, and for localized soft tissue disorders, they should be used only for intralesional injection.⁴²

Glucocorticoid Therapy in Rheumatoid Arthritis

Glucocorticoids are a frequently applied medication in RA. In the past, more patients with RA seemed to be given concomitant glucocorticoids in the United States than in Europe—54% versus 27%^{43,44}—whereas more recent data suggest that 38% of RA patients in the United States use glucocorticoids⁴⁵ versus up to 55% of German RA patients.⁴⁶ Aims of this therapy include reduction of signs and symptoms and inhibition of joint damage.

Signs and Symptoms

As can be seen in Table 60-4, RA is the only disease in which glucocorticoid therapy is often started and maintained at a low dose as additional therapy. The rationale for this therapy is a probable, relative insufficiency of the adrenal gland in patients with active RA.³¹ Glucocorticoids are highly effective for relieving symptoms in patients with active RA in doses of less than 10 mg/day. Many

3, Basic part of therapeutic strategy.

patients become functionally dependent on this therapy, however, and continue it over the long term.⁴⁷ A review of seven studies (253 patients) concluded that glucocorticoids, when administered for approximately 6 months, are effective for the treatment of RA.⁴⁸ After 6 months of therapy, the beneficial effects of glucocorticoids seem to diminish. If this therapy then is tapered off and stopped, however, patients often—over some months—experience aggravation of symptoms.

Radiologic Joint Damage: Glucocorticoids as DMARDs

In 1995, joint-preserving effects of 7.5 mg of prednisolone daily for 2 years were described in patients with RA of short and intermediate duration who also were treated with DMARDs. The group of RA patients participating in this randomized, placebo-controlled trial was heterogeneous, not only with respect to disease duration, but also with respect to stages of the disease and types and dosages of DMARDs.⁴⁹ In another trial published in 1997, patients with early RA were randomly assigned to step-down therapy with two DMARDs (sulfasalazine and methotrexate) and prednisolone (start 60 mg/day, tapered in six weekly steps to 7.5 mg/day and stopped at 34 weeks) or to sulfasalazine alone. In the combined drug strategy group, a statistically significant and clinically relevant effect in retarding joint damage was shown compared with the effect of sulfasalazine alone.⁵⁰ In an extension of this study, long-term (4 to 5 years) beneficial benefits were shown regarding radiologic damage after the combination strategy.⁵¹ It has been hypothesized that the superior effect of the combination therapy in this trial can be ascribed to prednisolone because in three double-blind, randomized trials, the effect of the

combination of methotrexate and sulfasalazine was not superior to that of either drug alone.⁵²⁻⁵⁴

In a German study, 200 patients with early RA were treated with methotrexate or intramuscular gold and were randomly assigned to additional treatment with 5 mg of prednisolone or placebo. After 2 years, progression of radiologic damage proved to be less in the prednisolone-treated patients than in those treated with placebo.⁵⁵ In 2002, results of the Utrecht study on the effects of prednisolone in DMARD-naïve patients with early RA were published. This is the only placebo-controlled trial in which prednisolone was applied as monotherapy as the first step. The progression of radiologic joint damage was inhibited by 10 mg of prednisolone daily in these patients (who received DMARD therapy only as rescue).⁵⁶

The Utrecht study reported a 40% decreased need for intra-articular glucocorticoid injections, a 49% decreased need for acetaminophen use, and a 55% decreased need for nonsteroidal anti-inflammatory drugs (NSAIDs) in the prednisolone group compared with the placebo group. This indicates that in clinical trials evaluating the clinical effects of DMARDs or glucocorticoids, additional therapies should be taken into account. In an extension of this study, at 3 years after the end of the study and 2 years after tapering off and stopping the prednisolone therapy, beneficial radiologic benefits of prednisolone were still present (Figure 60-7).⁵⁷

In another 2-year study in 250 patients with early RA, 7.5 mg/day of prednisolone added to DMARD therapy retarded joint damage and increased the remission rate compared with placebo added to DMARDs.⁵⁸ Even in an intensive treat-to-target methotrexate-based strategy in early RA, prednisone enhanced clinical efficiency and reduced erosive joint damage.^{58a}

Figure 60-7 Cumulative probability plot of mean yearly radiographic progression over 3 years since the end of the original 2-year study in patients originally randomized to receive prednisone therapy (triangles) or placebo (circles).^{56,57} At the end of the 2-year trial, the prednisone therapy was tapered down and stopped, if possible. Y-axis, Yearly progression of radiographic joint damage according to the van der Heijde modification of the Sharp method.

Negative studies on the effects of glucocorticoids on radiologic damage have also been published,⁵⁹⁻⁶¹ but in early RA, evidence of glucocorticoid joint-sparing effects, which persist after therapy is stopped, seems convincing, thus classifying glucocorticoids as DMARDs. A meta-analysis on radiographic outcome analyzed 15 studies (two with negative results) that included a total of 1414 patients. Because different methods had been used in the individual trials, radiographic scores were expressed as a percentage of the maximum possible score for the specific radiographic method used. The standardized mean difference in progression was 0.40 in favor of strategies using glucocorticoids (95% confidence interval, 0.27 to 0.54). This was considered a conservative estimate because the most conservative estimate of the difference in each study had been chosen.⁶²

It is still unknown, however, whether glucocorticoids can also inhibit progression of erosion in RA of longer duration than 2 years. A so-called window of opportunity may exist in the treatment of RA.⁶³ If this window is present, effective treatment of early RA with glucocorticoids and DMARDs may result in an effect that lasts for a long time and in disease that is easier to control, whereas if effective treatment starts later, this opportunity may be lost, resulting in more difficult control of the disease with inflammation fueled by joint damage. Most studies on glucocorticoids and radiologic damage employed a dose of 5 to 10 mg/day of prednisone equivalent during 2 years, but a scheme starting with 60 mg/day tapered off and stopped within 34 weeks also was effective. In addition, because glucocorticoid-induced osteoporosis and peptic ulcer complications (if glucocorticoids are combined with nonsteroidal anti-inflammatory drugs [NSAIDs]) can be prevented much more effectively now than some decades ago, the joint-protective effect of prednisolone in RA during the first 2

years of the disease in a dose of 5 to 10 mg daily is a relevant finding.

The joint-sparing effect of glucocorticoids probably is based on inhibition of proinflammatory cytokines such as IL-1 and TNF,⁶⁴ which stimulate osteoblasts and T cells to produce receptor activator of nuclear factor κ B (RANK) ligand. This binds to RANK on osteoclast precursor cells and on mature osteoblasts, leading to activation of osteoclasts, which are responsible for bone resorption, periarticular osteopenia, and formation of bone erosions in RA.

A toxicity index score for DMARDs was published (based on symptoms, laboratory abnormalities, and hospitalization data) after evaluation of 3000 patients with more than 7300 patient-years from the Arthritis, Rheumatism, and Aging Medical Information System (ARAMIS) database.⁶⁵ Although this score has not been validated and is influenced by confounding-by-indication, it gives an impression of the relative toxicity of glucocorticoids. It is comparable with that of other immunosuppressive medications used in RA, such as methotrexate and azathioprine. A review also showed that the incidence, severity, and impact of adverse effects of low-dose glucocorticoid therapy in RA trials were modest and suggested that probably many of the well-known adverse effects of glucocorticoids are predominantly associated with high-dose treatment.⁶⁶

Because many questions remain to be answered, such as how the effects of glucocorticoids compare with those of high dosages of methotrexate or of TNF blockers, and for how long glucocorticoids should be prescribed and in what dosages, the final place of glucocorticoid therapy in RA has to be clearly determined. Nevertheless in early RA the use of glucocorticoids generally has been accepted.^{66a} Guidelines on how to use (low-dose) glucocorticoids and how to monitor this therapy have been developed.^{67,68}

Prevention of Early (Rheumatoid) Arthritis Development with Glucocorticoids

Recently, trials have been done to try to prevent arthralgia or early arthritis from progressing to chronic arthritis. In patients with (very) early arthritis or individuals with arthralgia and antibodies to citrullinated proteins or rheumatoid factor, intramuscular glucocorticoid injections did not prevent arthritis development in two placebo-controlled trials,^{69,70} but in another placebo-controlled double-blind trial these injections postponed the need for DMARDs and prevented 1 in 10 patients from progressing into RA at assessment at 12 months.⁷¹ These results are preliminary and nonconclusive, and it is clear that further research is needed.

Chronobiology

The rheumatoid inflammatory process and symptoms have a diurnal rhythm. Early in the morning, patients experience the most extensive joint stiffness and other symptoms and signs; this is due to the long rest period during the night that facilitates edema formation around inflamed joints and the circadian rhythm of cortisol (see Figure 60-6). In patients with RA with low or medium disease activity, serum cortisol maximum and minimum shift to earlier times of the day and night, whereas in patients with high

disease activity, the circadian rhythm is markedly reduced or even lost.

The timing of glucocorticoid administration may be important for efficacy and side effects. Older data in the literature on this topic are ambiguous.^{72,73} Recently, a trial was performed with a newly developed modified-release prednisone tablet that releases prednisone about 4 hours after ingestion. When it was taken in the evening, thus adapting its release to circadian increases in proinflammatory cytokine concentrations, symptoms of RA early in the morning were lessened compared with those reported when the same dose of prednisone was taken early in the morning. This 3-month double-blind trial included RA patients with a duration of morning stiffness of 45 minutes or longer, a pain score of 30 mm or less on a 100-mm visual analog scale, three or more painful joints, one or more swollen joints, and an erythrocyte sedimentation rate (ESR) of 28 mm or greater or a C-reactive protein concentration 1.5 times or more the upper limit of normal, who were on glucocorticoids at least 3 months with a stable daily dose of 2 to 10 mg prednisone equivalent for at least 1 month. Patients were randomized to continue their prednisone or to switch to modified-release prednisone in a double-dummy way. At the end of the trial, the difference in duration of morning stiffness was about 30 minutes, in favor of the modified-release prednisone group. However, no differences were noted in all other variables of disease activity between the two groups. The safety profile did not differ between treatments.⁷⁴ Longer-term benefits and risks of this preparation and application in other inflammatory rheumatic diseases have yet to be investigated.⁷⁵

Other Developments to Improve the Therapeutic Ratio of Glucocorticoids

In addition to guidelines put forth to improve the clinical use of existing glucocorticoids,^{67,68} other formulations have been and are being developed. Deflazacort,⁷⁶ an oxazoline derivative of prednisolone introduced in 1969, was initially thought to be as effective as prednisone while inducing fewer adverse events, but there was the issue of the real equivalence ratio compared with prednisone⁷⁷; this drug has not represented a major breakthrough. Knowledge about the mechanisms of glucocorticoids (transrepression and transactivation leading, respectively, to predominantly beneficial effects and adverse effects; see earlier) led to the development of selective glucocorticoid receptor agonists or dissociating glucocorticoids,⁷⁸ but as yet they have not entered the market. Glucocorticoid preparations releasing nitric oxide, the so-called nitrosteroids, could induce stronger anti-inflammatory effects because nitric oxide has anti-inflammatory effects too.⁷⁹ These drugs have to be tested in patients yet. The drug combination prednisolone and dipyr-idamole has been reported to boost and extend the net glucocorticoid effect in laboratory models.⁸⁰ The next required step will be to demonstrate the improved therapeutic ratio in patients in adequate comparative clinical trials by assessing predefined beneficial effects and adverse effects in a standardized way.⁸¹ Liposomes containing glucocorticoids and targeted to integrins expressed on endothelial cells at sites of inflammation have been studied; these deliver their glucocorticoids specifically at sites of

inflammation.⁸² Their selective biodistribution might allow for less frequent and lower dosing, which could result in an improved therapeutic ratio. The safety of liposomal prednisolone has been evaluated in a small group of RA patients, and the results (up until now published only as an abstract) seem promising.⁸³ All of these new applications have to be tested further before they can be used in daily clinical practice.

Alternate-Day Regimens

For oral, long-term use of glucocorticoid therapy, alternate-day regimens have been devised in an attempt to alleviate the undesirable side effects, such as hypothalamic-pituitary-adrenal axis suppression. Alternate-day therapy uses a single dose administered every other morning, which is usually equivalent to, or higher than, twice the usual or pre-established daily dose. The rationale for this regimen is that the body, including the hypothalamic-pituitary-adrenal axis, is exposed to exogenous glucocorticoid only on alternate days. This rationale makes sense only for usage of a class and dosage of a glucocorticoid that suppresses the hypothalamic-pituitary-adrenal axis activity for less than 36 hours after a single dose. Another prerequisite is that the patient should have a responsive hypothalamic-pituitary-adrenal axis that is not chronically suppressed by previous glucocorticoid regimens. The alternate-day schedule does not work in patients on long-term medium- or high-dose glucocorticoids suppressing hypothalamic-pituitary-adrenal axis activity for longer than 36 hours.

Alternate-day therapy is unsuccessful in most patients who require glucocorticoids. Patients with RA often experience exacerbation of symptoms on the second day. This experience is in line with the clinical impression that a single dose of glucocorticoids daily is less effective in RA than half that dose, given twice daily. In giant cell arteritis, alternate-day glucocorticoid therapy also is less effective than daily administration.^{84,85} Generally, alternate-day regimens are used rarely in rheumatology today, except in patients with juvenile idiopathic arthritis, in whom alternate-day glucocorticoid usage results in less inhibition of body growth than is associated with daily usage.⁸⁶ If treatment has been initiated with daily administration, the change to alternate-day therapy preferably should be made after the disease has stabilized.

Glucocorticoid Sensitivity and Resistance

A small proportion of patients does not react favorably to glucocorticoids or even fails to respond to high doses. Also, susceptibility to adverse effects of glucocorticoids varies widely. Several different factors are involved in the variability of glucocorticoid sensitivity in patients with rheumatic diseases, and an understanding of the mechanisms involved might eventually allow their modulation. Potential mechanisms of glucocorticoid resistance in inflammatory diseases have been reviewed extensively.⁸⁷

Hereditary glucocorticoid resistance (rare) and increased susceptibility to glucocorticoids have been related to specific polymorphisms of the glucocorticoid receptor gene. The glucocorticoid receptor exists as α and β isoforms, but only the α isoform binds glucocorticoids. The β isoform

Table 60-5 Glucocorticoid Tapering Scheme to Hand Out to Patients*

	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
Period 1	High	High	High	High	Low	High	High
Period 2	High	Low	High	High	High	Low	High
Period 3	High	Low	High	Low	High	Low	High
Period 4	Low	High	Low	High	Low	High	Low
Period 5	Low	High	Low	Low	Low	High	Low
Period 6	Low	Low	Low	High	Low	Low	Low
Period 7	Low	Low	Low	Low	Low	Low	Low

*At each consecutive period (e.g., 1 week or some weeks), the number of days during which a low dose should be taken increases by 1. After completion of period 7, the next step in tapering can be taken; the dose called “low” during the previous 7 periods now is “high,” and so on. In case of aggravation of symptoms, the patient should not diminish the dose and should contact the specialist.

functions as an endogenous inhibitor of glucocorticoids and is expressed in several tissues. Glucocorticoid resistance has been associated with enhanced expression of this β receptor, but this is unlikely to be an important mechanism for glucocorticoid resistance because in most cells, apart from neutrophilic granulocytes, expression of the β receptor is much less than that of the α receptor.⁸⁷ The protein lipocortin-1 (or annexin-1) inhibits eicosanoid synthesis. Glucocorticoids are thought to stimulate lipocortin-1. In patients with RA, autoantibodies to lipocortin-1 have been described. The titers in these patients correlate with the height of maintenance doses of glucocorticoids, suggesting that these antibodies may lead to glucocorticoid resistance.

Although glucocorticoids exert most of their immunosuppressive actions through inhibition of cytokine production, high concentrations of cytokines, especially IL-2, antagonize the suppressive effects of glucocorticoids in a dose-dependent manner.⁷⁷ The balance is usually in favor of glucocorticoids, but high local concentrations of cytokines may result in localized glucocorticoid resistance that cannot be overridden by exogenous glucocorticoids. Also, the macrophage migration inhibitory factor may play a role in steroid resistance in RA. This proinflammatory cytokine is involved in TNF synthesis and T cell activation, suggesting a role in the pathogenesis of RA. Macrophage migration inhibitory factor is suppressed by higher concentrations of glucocorticoids, but it is induced by low concentrations, leading to stimulation of inflammation.⁷⁸ Other possible mechanisms of glucocorticoid resistance include activation of mitogen-activated protein kinase pathways by certain cytokines, excessive activation of the transcription factor activator protein-1, reduced histone deacetylase-2 expression, and increased P-glycoprotein-mediated drug efflux.⁸⁷ Also, drugs may play a role in glucocorticoid sensitivity and resistance (see also the section on drug interactions). Sulfasalazine increases the sensitivity of immune cells for glucocorticoids and thus might be a future option for preventing or treating glucocorticoid resistance.¹³ Mifepristone is an antiprogesterone drug and glucocorticoid receptor antagonist; chlorpromazine inhibits glucocorticoid receptor-mediated gene transcription.⁸⁸

Glucocorticoid Withdrawal Regimens

Because of potential side effects, glucocorticoids usually are tapered off as soon as the disease being treated is under control. Tapering must be done carefully to avoid recurrent activity of the disease and, infrequently, cortisol deficiency resulting from chronic hypothalamic-pituitary-adrenal axis

suppression. Gradual tapering permits recovery of adrenal function. There is no best scheme based on controlled, comparative studies for tapering glucocorticoids. Tapering depends on the individual disease, the disease activity, doses and duration of therapy, and clinical response, which also depends on each individual's glucocorticoid sensitivity. Only generic guidelines can be offered. To taper the dose of prednisone, decrements of 5 to 10 mg every 1 to 2 weeks can be used when the prednisone dose is more than 40 mg/day, followed by 5-mg decrements every 1 to 2 weeks at a dose between 40 and 20 mg/day, and finally 1 to 2.5 mg/day decrements every 2 to 3 weeks at a prednisone dose of less than 20 mg/day. Another scheme is to taper 5 to 10 mg every 1 to 2 weeks down to 30 mg/day of prednisone, and when the dose is less than 20 mg/day, to taper 2.5 to 5 mg every 2 to 4 weeks down to 10 mg/day; thereafter, the dose is tapered 1 mg each month or 2.5 mg (half a 5-mg tablet of prednisolone) each 7 weeks. For tapering every 7 weeks or over longer periods, a printed schedule can be given to the patient, such as the one shown in Table 60-5.

Adaptations of Glucocorticoid Doses, Stress Regimens, and Perioperative Care

Patients on long-term low-dose glucocorticoid medication have suppressed adrenal activity and should be advised to double their daily glucocorticoid dose or to increase the dose to 15 mg prednisolone or equivalent if they develop fever attributed to infection, and to seek medical help. In case of major surgery, given the unreliable prediction of adrenal suppression on the basis of duration and dose of glucocorticoid therapy (see the section on effects of glucocorticoids on the hypothalamic-pituitary-adrenal axis), many physicians recommend “stress doses” of glucocorticoids for patients with low risk of adrenal suppression. The scheme of 100 mg of hydrocortisone intravenously just before surgery, followed by an additional 100 mg every 6 hours for 3 days, is based on anecdotal information and is not always necessary.^{89,90} A scheme with a lower dose, possibly reducing the risk of postoperative bacterial infectious complications, is to infuse continuously 100 mg of hydrocortisone intravenously on the day of surgery, followed by 25 to 50 mg of hydrocortisone every 8 hours for 2 or 3 days. Another option is to administer the usual dose of oral glucocorticoid orally or (the equivalent) parenterally on the day of surgery, followed by 25 to 50 mg of hydrocortisone every 8 hours for 2 or 3 days.

In cases of minor surgery, it is probably sufficient to double the oral dose or to increase the dose to 15 mg of

prednisolone or equivalent for 1 to 3 days. No comparative randomized studies on different perioperative glucocorticoid stress schemes have been published, however. Because in glucocorticoid-induced secondary adrenal insufficiency, aldosterone secretion is preserved, mineralocorticoid therapy is unnecessary, in contrast to in primary adrenal insufficiency.

Glucocorticoid-Sparing Agents

For most inflammatory rheumatic diseases, including SLE, vasculitis, RA, and myositis, other immunomodulatory drugs are often added to therapy with glucocorticoids, such as azathioprine and methotrexate, and especially in case of systemic vasculitis, cyclophosphamide. For these indications, biologic agents are increasingly used.⁹¹ An exception is polymyalgia rheumatica, which is managed primarily with glucocorticoids alone. Combination therapy is applied early in the disease when the disease is one for which it is known that the effect of the combination is better than that of glucocorticoids alone (e.g., in the case of systemic vasculitis), or if the disease (e.g., inflammatory myositis) seems resistant to high initial doses of glucocorticoids.

If at a later stage of the disease, immunomodulatory drugs are added to therapy with glucocorticoids to enable further reduction of the dose to decrease the risk of side effects, these immunomodulatory drugs are termed *glucocorticoid-sparing agents*. For this purpose, azathioprine and methotrexate are often used, although any drug that has an additive or synergistic effect in suppressing the disease, enabling reduction of the glucocorticoid dose, could be used as a glucocorticoid-sparing agent.

Glucocorticoid Pulse Therapy

Glucocorticoid pulse therapy is used in rheumatology, especially for remission induction or treatment of flares of inflammatory rheumatic disorders and vasculitides (see Table 60-4). In RA, pulse therapy is applied to treat serious complications of the disease and to induce remission in active disease, often during the initiation phase of a (new) DMARD strategy. In the latter patients, pulse therapy with schemes of 1000 mg of methylprednisolone given intravenously has been proven effective in many studies. The beneficial effect generally lasts about 6 weeks, with large variation in the duration of the effect.⁹² It does not seem sensible to apply pulse therapy in active RA, unless a change in the therapeutic strategy (i.e., in second-line antirheumatic treatment) aims to stabilize over the long term any remission induced by the pulse therapy. Short-term effects of pulse therapy in patients with established, active RA at various dimensions of health status closely resemble the long-term effects of effective conventional DMARD therapy, such as methotrexate, in patients with early RA.⁹³ In 144 patients with biopsy-confirmed giant cell arteritis, of whom 91 were seen initially with visual loss and 53 without visual loss, no evidence was found that intravenous glucocorticoid pulse therapy (usually 150 mg dexamethasone sodium phosphate every 8 hours for 1 to 3 days) was more effective than high daily doses (80 to 120 mg) of oral prednisone in preventing visual deterioration.⁹⁴

The risk of adverse effects of pulse therapy is not the same for all rheumatic disorders. In patients with SLE, osteonecrosis and psychosis seem to be more frequent side effects of pulse therapy compared with those seen in patients with RA.⁹³ Osteonecrosis and psychosis also can be complications of SLE itself, however. Contraindications for pulse therapy include pregnancy and lactation, infection, current peptic ulcer disease, glaucoma, badly controlled hypertension, and diabetes mellitus. In cases with a family history of glaucoma or well-controlled hypertension or diabetes mellitus, pulse therapy can be applied with checks, respectively, of eye and blood pressure and of blood glucose values.

Intralesional and Intra-articular Glucocorticoid Injections

Injections with glucocorticoids are widely used for arthritis (see Table 60-4), tenosynovitis, bursitis, enthesitis, and compression neuropathies such as carpal tunnel syndrome.⁴² Generally, the effect occurs within days; it can be long-lasting, but if the underlying disease is active, the effect is of short duration. Administration of a local anesthetic concurrently with intra-articular or soft tissue injection of a glucocorticoid may provide immediate pain relief.

Soluble glucocorticoids (e.g., phosphate salts) have a more rapid onset of action with probably less risk of subcutaneous tissue atrophy and depigmentation of the skin when given intralesionally. Insoluble glucocorticoids are longer acting and might further decrease the soft tissue fibrous matrix, so they should be used with caution in places with thin skin, especially in elderly patients and in those with peripheral vascular disease. Insoluble glucocorticoids are more safely given into deep sites. Short-acting soluble glucocorticoids can be mixed with long-acting insoluble glucocorticoids to combine rapid onset with long-acting effect.

The effect of intra-articular glucocorticoid injection probably depends on several factors: the underlying disease (e.g., RA, osteoarthritis), the treated joint (size, weight bearing, or non-weight bearing), the activity of arthritis, the volume of synovial fluid in the joint to be treated,⁴⁶ the application of arthrocentesis (synovial fluid aspiration) before injection, the choice and dose of the glucocorticoid preparation, application of rest to the injected joint, and the injection technique used. The effects of injections seem to be less favorable in osteoarthritis than in RA.⁹⁵ Arthrocentesis before injection of the glucocorticoid preparation reduces the risk for relapse of arthritis. Triamcinolone hexacetonide, which, among the injectable glucocorticoids, is the least soluble preparation, shows the longest effect.

Theoretically, rest of the injected joint minimizes leakage of the injected glucocorticoid preparation into the systemic circulation (via the hyperemic, inflamed synovium by enhanced pressure in the joint during activity), minimizes the risk of cartilage damage, and enhances repair of inflammatory tissue damage. Advice and procedures for the postinjection period in terms of activity vary from no restrictions, to minimal activity of the injected joint for a couple of days, to bed rest for 24 hours after injection of a knee joint or splinting of injected joints. Based on the literature, no definite evidence-based recommendations can be made, but it

seems prudent to rest and to not overuse the injected joint for several days, even if pain is relieved.

It is recommended that intra-articular glucocorticoid injections be repeated no more often than once every 3 weeks, and that they be given no more frequently than three times a year in a weight-bearing joint (e.g., the knee) to minimize glucocorticoid-induced joint damage. This recommendation seems sensible, but no definitive clinical evidence is available to support it. As one would expect, accuracy of steroid placement influences the clinical outcome of glucocorticoid injections into the shoulder and probably into other joints as well.⁹⁶ This is important because it is estimated that a few more than half of shoulder injections are inaccurately placed.^{96,97} The reported infection rate of joints after local injection with glucocorticoids is low, ranging from 1 case in 13,900 to 1 in 77,300 injections.^{98,99} Introduction of disposable needles and syringes has helped reduce the risk. In a 3-year prospective study in an urban area of 1 million people in the Netherlands, bacterial infections were detected in 214 joints (including 58 joints with a prosthesis or osteosynthetic material) of 186 patients; only 3 of these joint infections were attributed to an intra-articular injection.¹⁰⁰

Other adverse effects of local glucocorticoid injections include systemic adverse effects of the glucocorticoid, such as disturbance in the menstrual pattern, hot flush-like symptoms the day of or the day after injection, and hyperglycemia in diabetes mellitus.⁴² Local complications include subcutaneous fat tissue atrophy (especially after improper local injection), local depigmentation of the skin, tendon slip and rupture, and lesions to local nerves.⁴²

Table 60-6 Adverse Effects of Glucocorticoids

System	Adverse Effect
Skeletal	Osteoporosis, osteonecrosis, myopathy
Gastrointestinal	Peptic ulcer disease (in combination with nonsteroidal anti-inflammatory drugs), fatty liver
Immunologic	Predisposition to infection, suppressed delayed hypersensitivity (Mantoux test)
Cardiovascular	Fluid retention, hypertension, accelerated arteriosclerosis, arrhythmias
Ocular	Glaucoma, cataract
Cutaneous	Skin atrophy, striae, ecchymoses, impaired wound healing, acne, buffalo hump, hirsutism
Endocrine	Cushingoid appearance, diabetes mellitus, changes in lipid metabolism, enhanced appetite and weight gain, electrolyte abnormalities, hypothalamic-pituitary-adrenal axis suppression, suppression of gonadal hormones
Behavioral	Insomnia, psychosis, emotional instability, cognitive effects

ADVERSE EFFECTS AND MONITORING

Given the diversity of their mechanisms and sites of action, it is not surprising that glucocorticoids can cause a wide array of adverse effects (Table 60-6 and Figure 60-8). Most of these adverse effects cannot be avoided. However, the risk of most complications is dosage and time dependent; minimizing the quantity of glucocorticoid minimizes the risk of complications.⁶⁸ Dose-related patterns of adverse

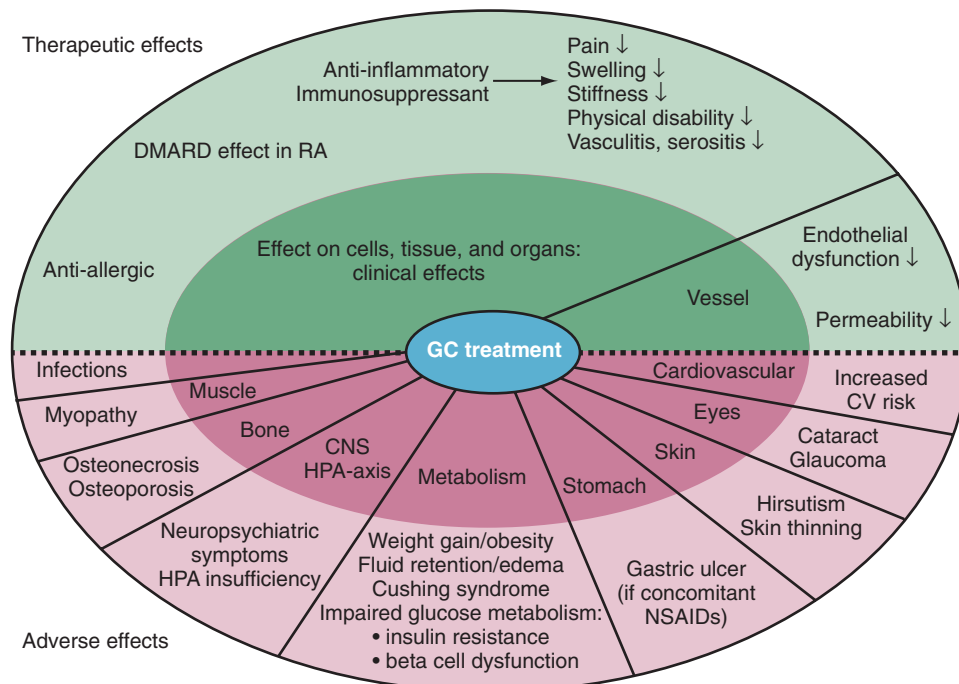

Figure 60-8 The spectrum of glucocorticoid (GC) therapy: beneficial effects in the upper green part of the figure, adverse effects in the lower red part. CNS, central nervous system; CV, cardiovascular; DMARD, disease-modifying antirheumatic drug; HPA, hypothalamic-pituitary-adrenal; NSAIDs, nonsteroidal anti-inflammatory drugs; RA, rheumatoid arthritis. (Adapted from Buttgeriet F, Burmester GR, Lipworth BJ: Optimised glucocorticoids therapy: the sharpening of an old spear, *Lancet* 365:801–803, 2005.)

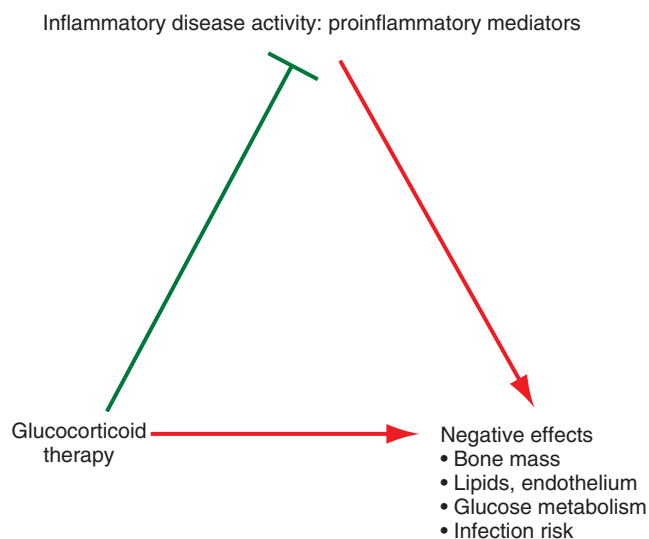

Figure 60-9 The interplay of glucocorticoid therapy, the inflammatory disease, and adverse effects, which, in combination with bias by indication, makes it hard in not randomized trials or cohorts to discriminate the negative effects of glucocorticoids from negative effects of the disease itself.

effects of glucocorticoids have been described.¹⁰¹ Low-dose glucocorticoid therapy is safer than is commonly thought,⁶⁶ and medium- to long-term glucocorticoid therapy in RA is associated with limited toxicity compared with use of placebo,¹⁰² but sensitivity for adverse effects differs among individuals. It is a clinical observation that some patients develop adverse effects after small doses of glucocorticoids, whereas other patients receive high doses without serious adverse effects. Apparent individual susceptibility to adverse effects does not seem to always parallel individual susceptibility to beneficial effects. Osteoporosis, diabetes, and cardiovascular disease are ranked by both patients and rheumatologists among the most worrisome adverse effects of glucocorticoids.¹⁰³ However, the frequency and the severity of glucocorticoid-related adverse effects have seldom been studied systematically. A problem for nonrandomized studies looking at glucocorticoid-related adverse effects is bias by indication: patients with severe disease tend to take glucocorticoids more frequently than those with less severe disease, and the disease as well as the glucocorticoids can cause unfavorable signs and symptoms¹⁰⁴; on the other hand, glucocorticoids decrease disease activity and therewith influence the frequency and severity of disease-associated signs and symptoms (Figure 60-9).

Skeletal Adverse Effects

Osteoporosis

Osteoporosis is a well-known adverse effect of glucocorticoids that can be prevented to a large degree. International and national guidelines to minimize the occurrence of glucocorticoid-induced osteoporosis have been developed and are updated periodically.^{105,106} Preventive and therapeutic management of glucocorticoid-induced osteoporosis is discussed in detail in Chapter 99. In short, following the actual guideline consists of providing calcium and vitamin

D supplementation and prescribing a bisphosphonate on indication.

Osteonecrosis

High-dose glucocorticoids given over longer periods are implicated as a cause of osteonecrosis, especially in children and patients with SLE. Vascular mechanisms seem to be involved. Ischemia possibly may be caused by microscopic fat emboli or impingement of the sinusoidal vascular bed by increased intraosseous pressure caused by fat accumulation. An early symptom is diffuse pain, which becomes persistent and increases with activity. Most frequently, hip or knee joints are involved; ankle and shoulder joints are involved less frequently. For early assessment, magnetic resonance imaging is the most sensitive investigative tool. Radionuclide bone scans provide less specific information. Plain radiographs are adequate only for follow-up. Treatment in the early stage includes immobilization and decreased weight bearing. Surgical decompression, joint replacement, or both follow this if needed. No preventive measures are known; awareness is the most important factor in early detection.

Myopathy

Weakness in proximal muscles, especially of the lower extremities, occurring within weeks to months after initiation of treatment with glucocorticoids, or after an increase in the dosage, may indicate steroid myopathy. It is often suspected but is infrequently found; it occurs almost exclusively in patients treated with high dosages (>30 mg/day prednisone or equivalent). Diagnosis is clinical and can be confirmed by a muscle biopsy specimen that reveals atrophy of type II fibers and lack of inflammation; no elevation of serum muscle enzymes is noted. Treatment consists of withdrawal of the glucocorticoid; if this is possible, a prompt decrease in symptoms may ensue. A rare syndrome of rapid-onset, acute myopathy, occurring within days after the start of high-dose glucocorticoids or pulse therapy, has been described; muscle biopsy specimens show atrophy and necrosis of muscle fibers.

Gastrointestinal Adverse Effects

Peptic Ulcer Disease

Data from the literature on upper gastrointestinal safety of oral glucocorticoids are inconclusive. The fact that glucocorticoids inhibit the production of COX-2 without hampering the production of COX-1 supports studies that found no increased risk. In other studies, a relative risk of serious upper gastrointestinal peptic complications of about 2 was found.¹⁰⁷ When glucocorticoids are used in combination with NSAIDs, the relative risk of peptic ulcer disease and associated complications is about 4.¹⁰⁸ Therefore in cases of co-medication with NSAIDs, consider co-treatment with a proton pump inhibitor, or prescribe a COX-1-sparing NSAID.⁶⁶ In patients treated with glucocorticoids without concomitant use of NSAIDs, no indication for gastrointestinal protective agents exists, unless other risk factors for peptic complications are present.

Other Gastrointestinal Adverse Effects

Although glucocorticoids usually are listed as one of the many potential causes of pancreatitis, evidence for such an association is weak and is difficult to separate from the underlying disease, such as vasculitis or SLE.¹⁰⁹ Asymptomatic and symptomatic colonization of the upper gastrointestinal tract with *Candida albicans* is increased in patients treated with glucocorticoids, especially when other risk factors are present, such as advanced age, diabetes mellitus, and concomitant use of other immunosuppressive agents. Glucocorticoids may mask symptoms and signs usually associated with the occurrence of intra-abdominal complications, such as perforation of the intestine and peritonitis (e.g., as a complication of diverticulitis), and can lead to a delay in diagnosis with increased morbidity and mortality.

Immunologic Adverse Effects

At high doses, glucocorticoids diminish neutrophil phagocytosis and bacterial killing in vitro, whereas in vivo, normal bactericidal and phagocytic activities are found. Monocytes are more susceptible; during treatment with medium to high doses of glucocorticoids, bactericidal and fungicidal activity in vivo and in vitro is reduced. These factors may influence the risk of infection. From epidemiologic studies, treatment with a daily dose of less than 10 mg of prednisone or equivalent seems to lead to no or an only slightly increased risk of infection; however, if doses of 20 to 40 mg daily are used, the risk of infection is increased (relative risk of 1.3 to 3.6).¹¹⁰ This risk increases with increased dose and duration of treatment.⁴⁵

In a meta-analysis of 71 trials involving more than 2000 patients with different diseases and different doses of glucocorticoids, an increased relative risk of infection of 2 was found. The risk varied according to the type of disease being treated. Five of these trials involved patients with rheumatic diseases and showed no increased risk (relative risk of 1).¹¹⁰ The same was found in a double-blind, placebo-controlled, 2-year trial in patients with early RA, in which the effect of 10 mg of prednisone daily was compared with that of placebo.⁵⁶ In one study, after adjustments were made for covariates, prednisone use dose dependently increased the risk of hospitalization for pneumonia.⁴⁵ In patients treated with glucocorticoids, especially at high doses, clinicians should anticipate infections with usual and unusual organisms, realizing that glucocorticoids may blunt classic clinical features, thus delaying diagnosis.

Cardiovascular Adverse Effects

Mineralocorticoid Effects

Some glucocorticoids have mineralocorticoid actions (see Table 60-1), including reduced renal excretion of sodium and chloride and increased excretion of potassium, calcium, and phosphate. This activity may lead to edema, weight gain, increased blood pressure, and heart failure (caused by reduced excretion of sodium and chloride); cardiac arrhythmia (resulting from increased excretion of potassium); or tetany and electrocardiographic changes (related to hypocalcemia).

Low doses of glucocorticoid are not a cause of hypertension, in contrast to higher doses.¹¹¹ No formal studies addressing the effects of glucocorticoids in previously hypertensive patients have been reported. Two randomized, controlled studies in patients with myocarditis and idiopathic cardiomyopathy showed no differences between placebo-treated or glucocorticoid-treated groups after 1 year or in survival at 2 and 4 years.^{112,113}

Atherosclerosis

Accelerated atherosclerosis and elevated cardiovascular risk have been reported in patients with SLE and in patients with RA.¹¹⁴ Glucocorticoids may enhance cardiovascular risk via their potentially deleterious effects on lipids,¹¹⁵ glucose tolerance, insulin production and resistance, blood pressure, and obesity.¹¹⁴ However, these conditions seem not to be adverse effects of low-dose glucocorticoids. Furthermore, atherosclerosis itself has been recognized as an inflammatory disease of arterial walls, for which glucocorticoids may be beneficial; glucocorticoids have been found to inhibit macrophage accumulation in injured arterial walls in vitro, possibly resulting in attenuation of the local inflammatory response.¹¹⁶ Low-dose glucocorticoids might also improve dyslipidemia associated with inflammatory disease.^{114,117-119} However, the effects on lipids and other cardiovascular risk factors of low-dose glucocorticoids in inflammatory diseases probably are different from those of medium and high doses of glucocorticoids,¹¹⁵ or those of glucocorticoid therapy in noninflammatory diseases. This, along with the interplay of disease activity, glucocorticoids, and adverse effects (see Figure 60-9), makes it difficult to judge the net adverse effects of glucocorticoids on cardiovascular risk and lipids.¹²⁰ The finding that a common haplotype of the glucocorticoid receptor gene is associated with heart failure, and that this association is mediated in part by low-grade inflammation, complicates this issue even further.¹²¹

Ocular Adverse Effects

Cataract

Glucocorticoids tend to stimulate the formation of posterior subcapsular cataract especially,¹²² but the risk of cortical cataract also seems increased, with an odds ratio of 2.6.¹²³ To some extent, the likelihood or severity of this adverse effect depends on dose and duration of treatment. In patients treated long term with glucocorticoids at a dosage of 15 mg or more of prednisone daily for 1 year, cataract is observed frequently; in patients receiving long-term therapy with less than 10 mg of prednisone daily, the percentage of cataract is less, but cataract may develop at dosages greater than 5 mg/day of prednisone equivalent.⁴⁶ These cataracts are usually bilateral but progress slowly. They may cause glare disturbance but usually cause little visual impairment, except at end stages.

Glaucoma

By increasing intraocular pressure, glucocorticoids may cause or aggravate glaucoma. Patients with a family history

of open-angle glaucoma and patients with high myopia are probably prone to develop this adverse effect, especially when receiving high doses of glucocorticoids; checks of intraocular pressure are then warranted. If increased, patients need to be treated with medications that reduce intraocular pressure, often for a prolonged period after stopping the glucocorticoid.¹²⁴ Topical application of a glucocorticoid in the eye has a more pronounced effect on intraocular pressure compared with systemic glucocorticoid therapy.¹²⁵

Dermal Adverse Effects

Clinically relevant adverse effects of glucocorticoids on skin include cushingoid appearance, easy bruising, ecchymoses, skin atrophy, striae, disturbed wound healing, acne, perioral dermatitis, hyperpigmentation, facial redness, mild hirsutism, and thinning of scalp hair. The physician often considers these changes to be of minor clinical importance, but they may be disturbing to the patient.¹⁰³ No reliable data on the exact frequency of these adverse effects are available, but these adverse effects are dependent on duration of therapy and dose.⁴⁶ Many physicians recognize immediately the skin of a patient who has been taking glucocorticoids on a long-term basis.

Endocrine Adverse Effects

Glucose Intolerance and Diabetes Mellitus

Glucocorticoids increase hepatic glucose production and induce insulin resistance by inhibiting insulin-stimulated glucose uptake and metabolism by peripheral tissues. Glucocorticoids probably also have a direct effect on beta cells of the pancreas, resulting in enhanced insulin secretion during glucocorticoid therapy. It may take only a few weeks before glucocorticoid-induced hyperglycemia occurs with low and medium glucocorticoid doses. One case-control, population-based study in previously nondiabetic subjects suggested an odds ratio of 1.8 for the need to initiate antihyperglycemic drugs during glucocorticoid therapy with doses of 10 mg or less of prednisone or equivalent per day. This risk increased with higher daily doses of glucocorticoids. The odds ratio was 3 for 10 to 20 mg, 5.8 for 20 to 30 mg, and 10.3 for 30 mg or more of prednisone or equivalent per day.¹²⁶

It is likely that risk is increased further in patients with other risk factors for diabetes mellitus, such as a family history of the disease, advanced age, obesity, and previous gestational diabetes. Postprandial hyperglycemia and only mildly elevated fasting glucose concentrations are characteristic of glucocorticoid-induced diabetes mellitus. Worsening of glycemic control can be expected in patients with established glucose intolerance or diabetes mellitus. Usually, glucocorticoid-induced diabetes is reversible when the drug is discontinued, unless clear glucose intolerance was pre-existent.

Fat Redistribution and Body Weight

One of the most notable effects of long-term endogenous or exogenous glucocorticoid excess is the redistribution of

body fat. Centripetal fat accumulation with thin extremities is a characteristic feature of patients exposed to long-term high-dose glucocorticoids. Potential mechanisms include increased conversion of cortisone to cortisol in visceral adipocytes, hyperinsulinemia, and changes in expression and activity of adipocyte-derived hormones and cytokines, such as leptin and TNF.¹²⁷ Protein loss resulting in muscle atrophy also contributes to the change in body appearance. Increased appetite influences body weight during glucocorticoid therapy, but patients with active inflammatory disease tend to lose weight, which can be prevented with disease control by drugs, including glucocorticoids. Trials in patients with RA given low-dose glucocorticoids for a prolonged period showed only minor effects on fat redistribution and body weight.^{55,56}

Dyslipidemia

See the earlier section, "Atherosclerosis."

Suppression of the Hypothalamic-Pituitary-Adrenal Axis

In the section on effects of glucocorticoids on the hypothalamic-pituitary-adrenal axis, mechanisms of chronic suppression of the hypothalamic-pituitary-adrenal axis by administration of exogenous glucocorticoids are described. In such a situation, acute discontinuation of glucocorticoid therapy may lead to acute adrenal insufficiency with possible circulatory collapse and death.^{11,128}

About 10 years after glucocorticoid therapy became available, the first well-documented case of adrenal insufficiency after withdrawal of exogenous glucocorticoid was reported.¹²⁹

Acute cessation of glucocorticoid therapy without tapering is indicated for corneal ulceration by herpes virus, which can lead rapidly to perforation of the cornea, and glucocorticoid-induced acute psychosis. In these patients, assessment of adrenal responsiveness on a corticotropin test seems prudent. Not all patients with a blunted cortisol response have signs or symptoms of adrenal insufficiency, however.

Clinical signs and symptoms of chronic adrenal hypofunctioning are nonspecific and include fatigue and weakness, lethargy, orthostatic hypotension, nausea, loss of appetite, vomiting, diarrhea, arthralgia, and myalgia. These symptoms partially overlap glucocorticoid withdrawal symptoms, such as fatigue, arthralgia, and myalgia. When in doubt, measurements of serum cortisol levels and the corticotropin stimulation test are indicated. Glucocorticoid withdrawal symptoms are sometimes difficult to discriminate from symptoms of the primary disease, such as polymyalgia rheumatica. Because mineralocorticoid secretion remains intact via the renin-angiotensin-aldosterone axis, serious electrolyte disturbances are uncommon.

Adverse Behavioral Effects

Glucocorticoid treatment is associated with a variety of behavioral symptoms. Although most attention has been directed toward specific dramatic disturbances collectively described under the term *glucocorticoid psychosis*, less florid effects also occur that may cause distress to a patient and

warrant medical attention.¹⁰³ Minor behavioral manifestations may also occur on withdrawal of glucocorticoids.

Steroid Psychosis

Overt psychosis is rare and usually is associated with high-dose glucocorticoids or glucocorticoid pulse therapy, but psychosis may also be a complication of the disease itself, especially SLE. This makes it difficult to distinguish in an individual SLE patient with psychosis whether the condition is a complication of the disease, of the therapy, or of both.

Isolated psychosis is seen in about 10% of glucocorticoid-related cases, and in most patients, affective disorders are present as well. Around 40% of cases of glucocorticoid-induced psychosis manifest as depression, whereas mania, often dominated by irritability, is predominant in 30% of cases.¹³⁰ Psychotic symptoms usually start just after initiation of treatment (60% within the first 2 weeks, 90% within the first 6 weeks), and remission after drug dose reduction or withdrawal follows the same pattern. Although the data are largely anecdotal, individuals developing steroid psychosis frequently have had prior evidence of some dissociative symptoms. Occasionally, remission occurs without dose reduction.

Minor Mood Disturbances

Glucocorticoids have been associated with a wide variety of low-grade disturbances, such as depressed or elated mood (euphoria), insomnia, irritability, emotional instability, anxiety, memory failure, and other cognition impairments. Although the symptoms may not become severe enough for a specific diagnosis, they warrant attention—not only because they cause distress to the patient, but also because they may interfere with evaluation and treatment of the underlying disease. Most physicians recognize the occurrence of such symptoms in many glucocorticoid-treated patients; these symptoms may occur in varying degrees in up to 50% of treated patients within the first week. The exact incidence in rheumatic patients exposed to the usual doses of glucocorticoids is unknown; most series dedicated to mood disturbances studied high doses.¹³¹ It is important to inform patients about these minor mood disturbances before starting glucocorticoid therapy.¹⁰³

Monitoring

Glucocorticoid-related adverse effects have seldom been studied systematically. Mostly based on expert and patient opinion, recommendations have been formulated for monitoring low-dose glucocorticoid therapy. The conclusion is that in daily practice, standard care monitoring for serious diseases warranting glucocorticoid therapy need not be extended for patients on low-dose glucocorticoid therapy, except for monitoring for osteoporosis (follow national guidelines) and baseline assessments of fasting blood glucose and of risk factors for glaucoma, as well as a baseline check for ankle edema.⁶⁷ Of course, for medium and high dosages, monitoring should be extended, not only to monitor for adverse effects of glucocorticoid therapy, but also to check for adverse effects of the concomitant medication and

complications of the severe disease; for these glucocorticoid dosages, monitoring guidelines are being developed. In these situations, next to good clinical practice monitoring, including for instance blood pressure measurements, checks of ocular pressure and urine glucose specifically seem indicated. For clinical trials on glucocorticoids, it is advised to monitor and report more comprehensively and to sample more data on the spectrum, incidence, and severity of adverse events of glucocorticoids.⁶⁷ If applied prudently, glucocorticoids are still one of the most relevant therapeutic tools in clinical medicine of the 21st century.

Future Directions

Although glucocorticoids have been used in clinical practice for many years, they still are the anchor drugs in autoimmune and inflammatory diseases and vasculitides. In contrast with their established use, there is a paucity of data on the spectrum, incidence, and severity of adverse effects of glucocorticoids at different dosages and in different diseases. To develop evidence-based guidelines and to evaluate the adverse effects of new compounds with glucocorticoid actions that are being developed, additional research into molecular mechanisms and continued collection of data are needed.⁶⁷

KEY POINTS

Methotrexate is one of the most durable and frequently used disease-modifying antirheumatic drugs (DMARDs) in monotherapy as well as the cornerstone of combination therapy for rheumatoid arthritis (RA).

Leflunomide, sulfasalazine, and hydroxychloroquine are effective therapies in RA and are commonly employed in combination therapy.

Although the precise mechanisms of action of the traditional DMARDs are incompletely understood, most have both anti-inflammatory and immunomodulatory actions.

Choice of DMARD therapy should be tailored to the individual patient, with attention given to age, fertility plans, concomitant medications, and comorbidities.

Toxicity from DMARD therapy can cause significant morbidity and rarely mortality; thus, appropriate dosing and monitoring for toxicity are essential.

Combination therapy in RA can be more effective than mono-DMARD therapy in groups of patients with early and established RA.

The appropriate timing and combinations of DMARD therapy in individual patients is still not defined.

METHOTREXATE

KEY POINTS

An important mechanism of action for methotrexate (MTX) is the upregulation of adenosine, which is a potent inhibitor of inflammation.

MTX is polyglutamated in cells, and this is responsible for its long therapeutic effect.

The effects of MTX may be enhanced by splitting the dose (within a 12-hour window) when levels greater than 15 mg/wk are used, or by using a subcutaneous route of administration.

Concomitant use of folic acid abrogates some of the side effects of MTX without decreasing efficacy.

The dose of MTX must be adjusted for reduced renal function.

Although rare, MTX pneumonitis is a serious and potentially fatal complication of therapy.

It would be difficult to overstate the importance of methotrexate (MTX) in the contemporary management of rheumatic disease and, in particular, rheumatoid arthritis (RA). Because of its antiproliferative effects, MTX was introduced

Traditional DMARDs: Methotrexate, Leflunomide, Sulfasalazine, Hydroxychloroquine, and Combination Therapies

AMY C. CANNELLA • JAMES R. O'DELL

more than 50 years ago to treat cancer. Over the last quarter century, it has become the disease-modifying antirheumatic drug (DMARD) of choice in the treatment of RA and is used in many other rheumatic diseases as well.

Chemical Structure

MTX is a structural analogue of folic acid and has substitutions in the pteridine group and para-aminobenzoic acid structure (Figure 61-1). The structure of folic acid (pteroylglutamic acid) consists of three elements: a multi-ring pteridine group, linked to a para-aminobenzoic acid, which is connected to a terminal glutamic acid residue.

Actions of Methotrexate

Because MTX is a folate analogue, it enters cells via a reduced folate carrier (RFC). Leucovorin competes with MTX for uptake using the same RFC; however, folic acid enters cells via another group of transmembrane receptors called folate receptors (FRs).¹ FRs may be upregulated in cells with increased metabolic activity, including synovial macrophages, and serve as a second conduit for MTX influx.^{2,3} MTX efflux occurs via members of the adenosine triphosphate (ATP)-binding cassette (ABC) family of transporters, specifically ABCC1-4 and ABCG2.⁴ Genetic polymorphisms may affect MTX transporter proteins (influx and efflux) and can result in a variable MTX response and toxicity profile.⁴ Furthermore, multidrug resistance proteins have been identified that transport MTX, folic acid, and leucovorin out of cells, leading to MTX resistance.⁵

Once inside the cell, naturally occurring folates as well as MTX undergo polyglutamation by the enzyme folylpolyglutamyl synthetase (FPGS). Polyglutamation of MTX (MTX-PG) is essential to prevent efflux of MTX, which easily occurs in the monoglutaminated state. MTX-PG has several key inhibitory effects on intracellular enzymes, which result in its postulated anti-inflammatory and anti-proliferative (immunosuppressive) mechanisms: (1) Inhibition of aminoimidazole carboxamide ribonucleotide (AICAR) transformylase (ATIC) results in increased intracellular and extracellular adenosine, (2) inhibition of thymidylate synthetase (TYMS) results in decreased pyrimidine

Figure 61-1 Chemical structure of folic acid and methotrexate.

synthesis, and (3) inhibition of dihydrofolate reductase (DHFR) results in inhibition of transmethylation reactions essential for cellular functioning (Figure 61-2).

Inhibition of ATIC by MTX-PG leads to accumulation of AICAR and ultimately to increased levels of adenosine. Three possible mechanisms are postulated and likely work in combination: (1) AICAR inhibition of adenosine monophosphate (AMP) deaminase leads to excess production of adenosine from AMP; (2) AICAR inhibition of adenosine deaminase (ADA) leads to decreased breakdown of adenosine to inosine; and (3) AICAR stimulation of the ecto-5'-nucleotidase converts extracellular AMP to adenosine⁶⁻⁸ (Figure 61-3).

Adenosine, a purine nucleoside, has been termed a “retaliatory metabolite” because of its tissue protective

functions after stressful injurious stimuli.⁹ Adenosine, a potent inhibitor of inflammation,⁹ induces vasodilation.^{10,11} Adenosine’s anti-inflammatory effects include regulation of endothelial cell inflammatory functions, including cell trafficking,^{10,11} counterregulation of neutrophils and dendritic cells,^{9,12} and cytokine modulation of monocytes and macrophages.⁹ Adenosine receptor ligation on monocytes and macrophages suppresses interleukin (IL)-12, a strong proinflammatory cytokine.¹³ Adenosine also suppresses the proinflammatory mediators tumor necrosis factor (TNF), IL-6, IL-8, macrophage inflammatory protein (MIP)-1 α , leukotriene (LT)B₄, and nitric oxide and enhances production of the anti-inflammatory mediators IL-10 and IL-1 receptor antagonist.¹⁴⁻¹⁹ Furthermore, adenosine receptor-mediated processes result in inhibition of the synthesis of collagenase, including tissue inhibitors of metalloproteinases.²⁰ In sum, adenosine appears to promote a self-limiting, healthy immune response, hastening the transition from neutrophil-mediated inflammation to a more efficient and highly specific dendritic cell-mediated response. Ultimately adenosine leads to the resolution of inflammation by downregulation of macrophage activation and promotes a shift from a T helper (Th)1 cell to a T helper (Th)2 cell response.⁹

Evidence that the anti-inflammatory effects of MTX are mediated through adenosine has accumulated in in vitro and in animal studies.²¹ However, owing to adenosine’s short blood half-life of 2 seconds and MTX’s long latent period for active metabolites that modulate adenosine, it has been difficult to demonstrate changes in blood adenosine levels directly related to MTX.²² Recent evidence using forearm blood flow as a surrogate marker for adenosine release in RA patients treated with MTX demonstrated that MTX inhibits deamination of adenosine and potentiates adenosine-induced vasodilation.²³ Demonstration of altered adenosine kinetics in patients treated with MTX coupled with adenosine’s known anti-inflammatory effects lends further credence to the hypothesis that MTX increases extracellular adenosine, which likely mediates some of the anti-inflammatory effects of MTX.

In addition to vasodilation, adenosine’s cardiovascular effects include negative inotropic and chronotropic cardiac

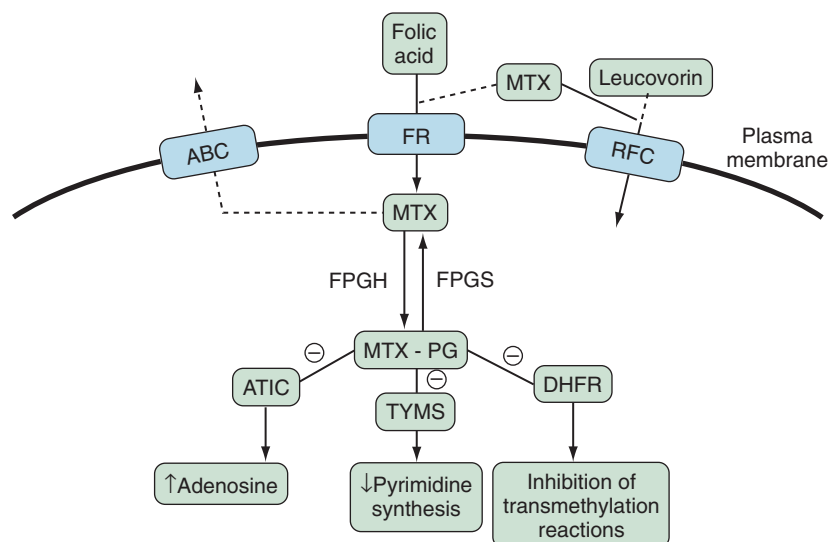

Figure 61-2 Methotrexate (MTX) enters cells primarily via the reduced folate carrier (RFC) but can use the folate receptor (FR). Once inside the cell, it becomes polyglutamated and can interfere with several cellular enzymes, including 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase (ATIC), thymidylate synthetase (TYMS), and dihydrofolate reductase (DHFR). ABC, ATP-binding cassette; FPGH, folylpolyglutamate hydrolase; FPGS, folyl-polyglutamyl synthetase; MTX-PG, polyglutamation of MTX.

MTX has been shown to inhibit proinflammatory cytokine IL-1 secretion and to induce the IL-1 receptor antagonist, effectively inhibiting cellular responses to IL-1.^{35,36} Soluble TNF receptor (sTNFR p75) synthesis upregulation has also been shown as a result of MTX treatment from cultured monocytic leukemia cells, which results in a diminished TNF inflammatory effect.³⁷ MTX also inhibits production and secretion of the proinflammatory cytokine, IL-6, by cultured human monocytes.^{38,39} Reverse transcriptase polymerase chain reaction has been used to study the effects of MTX on gene expression for lymphocytic cytokines.^{40,41} MTX increases anti-inflammatory Th2 cytokine (IL-4 and IL-10) gene expression and decreases proinflammatory Th1 cytokine (IL-2 and interferon [IFN]- γ) gene expression in peripheral blood mononuclear cells (PBMCs) of patients with RA.⁴¹

Prostaglandins (PGs) and leukotrienes (LTs) are important mediators of joint destruction in RA. MTX has been shown to modulate the inflammatory enzymes cyclooxygenase (COX) and lipoxygenase (LOX), and their products PG and LT. Thromboxane B₂ and prostaglandin E₂ activities were reduced in the whole blood of RA patients treated with MTX when compared with healthy controls.⁴² MTX also reduces LTB₄ synthesis by neutrophils, resulting in a decrease in total plasma LTB₄ levels in patients with RA treated weekly with MTX.⁴³ In addition to possible direct effects on COX and LOX, MTX has been shown to exert an inhibitory effect on neutrophil chemotaxis, which may result in a further reduction of these enzymes in sites of inflammation.⁴⁴

Tissue destruction at sites of inflammation is thought to be related to increased synthesis and activity of proteolytic enzymes released by inflammatory cells, particularly in RA. MTX treatment has been shown to reduce gene expression of collagenase, metalloproteinase-1, and stromelysin, and to upregulate expression of tissue inhibitor of metalloproteinase-1 (TIMP-1).⁴⁵ MTX may exert direct effects on messenger RNA (mRNA) for certain enzymes, such as collagenase. MTX also likely exerts indirect effects on gene expression via upstream cytokine modulation (IL-1 and IL-6), in the case of matrix metalloproteinase (MMP)-1 and TIMP-1.⁴⁶

Pharmacology

Absorption and Bioavailability

At low doses, MTX can be administered either orally or parenterally (subcutaneous or intramuscular), and absorption is rapid, peaking at 1 to 2 or 0.1 to 1 hour, respectively. The absorption of low-dose oral and parenteral MTX (<15 mg/wk) is roughly equivalent, but once the oral dose exceeds 15 mg/wk, absorption diminishes by as much as 30%.⁴⁷ Absorption is not reduced by concomitant food intake, except for milk, which may be inhibitory,⁴⁸ but may be reduced in the setting of intestinal pathology, such as inflammatory bowel disease or malabsorptive conditions.

Orally administered MTX is absorbed via the GI tract and passes through the liver via the portal vein; parenterally administered MTX passes through the liver via the hepatic artery. Although not prospectively studied in RA patients

receiving long-term MTX treatment, the parenteral route should have diminished potential for hepatotoxicity. This effect has been seen in a retrospective study wherein more elevations in transaminases were noted when oral MTX was administered to the same individuals versus when given parenterally.⁴⁹ A recent study at equivalent MTX doses showed improved efficacy in RA clinical end points for parenteral over orally administered MTX.⁵⁰

Forty-one RA patients who received 10 mg/m² of oral MTX had a mean bioavailability of 70% with a range of 40% to 100%.⁵¹ The mean absorption time was 1.2 hours. Four hours after MTX administration, synovial fluid concentrations equal serum levels.⁵¹ A recent study of high-dose oral MTX (median dose, 30 mg/wk) has shown that mean bioavailability is improved by splitting the dose by 8 hours compared with one single dose (0.90 and 0.76, respectively).⁵² The pharmacokinetics of subcutaneous MTX are equivalent to those of intramuscular MTX; maximum serum concentration is attained within 2 hours of injection by either route.⁵³ Also, bioavailability is equivalent between tablets and orally administered parenteral solution.⁵⁴

Distribution and Half-Life

MTX is 50% to 60% bound to plasma proteins and has a half-life of approximately 6 hours.⁵¹ An increase in free MTX caused by displacement from albumin by more highly protein-bound drugs such as aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and sulfonamides can occur. This is generally of limited clinical significance with low MTX doses because the increase in free MTX is usually only modest.

MTX accumulates in third space fluids, which can serve as a reservoir for redistribution into the circulation long after the last dose is administered.⁵⁵ Caution should be used when administering MTX to patients with pleural effusions or ascites. Furthermore, unexpectedly high levels of MTX have been seen in patients with bladder cancer who have undergone ileal conduit surgery owing to enhanced intestinal absorption through the newly fashioned conduit.⁵⁶

The biologically active form of MTX occurs after intracellular polyglutamation (MTX-PG). MTX undergoes up to five polyglutamations, and recent studies have looked at this aspect of MTX pharmacology. Once on a stable dose of MTX, the median time until 90% of the maximum steady-state concentration of MTX-PG was reached was found to be 27.5 weeks (range, 6.6 to 62.0 weeks).⁵⁷

Elimination

Most MTX is excreted in the urine within the first 12 hours after administration, except for MTX-PG. MTX undergoes some hepatic metabolism by the enzyme aldehyde oxidase to the 7-hydroxymethotrexate metabolite; this metabolite has unknown significance in RA. MTX and metabolites are excreted by the kidney by glomerular filtration and proximal tubular secretion but also undergo distal tubular reabsorption. The estimated median half-life of elimination of MTX-PG is 3.1 weeks (range, 0.94 to 4.1 weeks), and MTX-PG is undetectable at 15 weeks.⁵⁷ MTX-PG₃ is the most common subtype seen (30% of total MTX-PG) and has a median half-life elimination of 4.1 weeks.

Indications

Rheumatoid Arthritis. The efficacy of MTX in RA has been clearly established. Four well-designed, blinded, placebo-controlled trials⁵⁸⁻⁶¹ published in 1984 and 1985 had a tremendous impact on the treatment of RA. These trials varied in design and duration: Two of these trials used oral MTX and two used intramuscular (IM) MTX, two trials had a crossover and two were parallel, and the duration of treatment varied from 6 to 28 weeks. Although the design and duration of therapy in these trials varied, the conclusions did not, as all showed MTX to be superior to placebo in the short-term treatment of RA. A meta-analysis of these trials by Tugwell and coworkers⁶² showed that MTX-treated patients had a 37% greater improvement in swollen joint and tender joint scores, a 39% greater improvement in joint pain, and a 46% greater improvement in morning stiffness. MTX was generally well tolerated in these trials; withdrawal rates ranged from 0 to 32% and were mostly related to minor toxicities (i.e., stomatitis, nausea). Taken together, the results of these trials firmly established MTX as an effective therapy for the treatment of RA, at least in the short term.

Numerous trials have compared MTX with other DMARDs. A meta-analysis done by Felson and co-workers showed that MTX was superior to placebo, auranofin, and probably hydroxychloroquine (HCQ), and was comparable with penicillamine, sulfasalazine, and IM gold.⁶³ No trial has ever suggested that any other synthetic DMARD is superior to MTX.

Accumulating evidence suggests that the short-term benefit of most DMARDs is not sustained, and few patients continue to take these drugs after 3 years.^{64,65} MTX appears to have the best durability. Pincus and colleagues have shown that 60% of patients continued MTX at 5 years, compared with less than 25% for penicillamine, gold, HCQ, and azathioprine.⁶⁴ Of all the DMARDs, MTX appears to have the best efficacy-to-toxicity ratio.⁶³ However, despite all the favorable efficacy reports, MTX alone rarely induces remissions of RA, and it has become the cornerstone of combinations of DMARD therapies as discussed later.^{66,67}

Rheumatoid Arthritis–Related Conditions. MTX has been used successfully in treating Felty's syndrome⁶⁸ and the large granular lymphocyte syndrome when it is found in patients with RA.⁶⁹ Improvement in neutrophil count occurs within 4 to 8 weeks of MTX initiation in both cases. MTX has been used successfully in adult-onset Still's disease⁷⁰ and for the cutaneous vasculitis of RA.⁷¹

Juvenile Idiopathic Arthritis. MTX is efficacious in juvenile idiopathic arthritis. A definitive, randomized, placebo-controlled trial demonstrated that MTX at a dose of 10.0 mg/m² was superior to 5.0 mg/m² or placebo.⁷² Sixty-three percent of children receiving the higher dose (10.0 mg/m²) of MTX improved, compared with 32% in the lower-dose group (5.0 mg/m²) and 36% in the placebo group.

Psoriatic Arthritis (PsA). Numerous prospective and retrospective trials have showed a benefit for MTX in PsA.⁷³ The largest double-blind randomized trial compared weekly oral MTX with placebo, and showed statistically significant results only for physician global assessment of arthritis activity and the amount of affected skin surface area; however, this study was small and may have been underpowered to

detect differences in joint count, pain, and swelling.⁷⁴ Despite the paucity of randomized controlled trial data, MTX remains a commonly used systemic agent in the treatment of PsA.

Systemic Lupus Erythematosus (SLE). MTX has been shown to be efficacious in controlling cutaneous and/or articular manifestations of SLE, particularly in disease resistant to antimalarials or requiring high doses of systemic steroids.⁷⁵ Concomitant folic acid should be administered to abrogate the elevated levels of homocysteine that may be a side effect of MTX therapy, and is considered a risk factor for cardiovascular disease in SLE. The role of MTX in treating more severe SLE involvement, including renal, hematologic, or central nervous system disease, has not yet been established.⁷⁶ Extreme caution should be employed in patients with renal disease.

Vasculitis. MTX in conjunction with corticosteroids has shown efficacy in treating early and non-life-threatening granulomatosis with polyangiitis (formerly Wegener's granulomatosis), including upper airway disease and mild renal disease.⁷⁷⁻⁸⁰ In addition to induction of remission, MTX has been shown to maintain remission in granulomatosis with polyangiitis, although vigilance for relapse is warranted.⁸¹ Despite a lack of well-designed studies, MTX has been shown to be efficacious in corticosteroid-resistant Takayasu's arteritis⁸² and in relapsing polychondritis.⁸³

The use of MTX for polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) has been controversial. Multiple open-label studies have shown differing results. Recently, randomized, placebo-controlled trials (RCTs) of MTX in addition to corticosteroids in PMR and GCA have shown conflicting results.⁸⁴⁻⁸⁷ Thus, the routine use of MTX in either PMR or GCA has not been adopted, but some advocate for its use in an effort to more rapidly taper corticosteroid in those patients with intolerable side effects.

Inflammatory Myopathies. A review of the published reports of MTX and the inflammatory myopathies polymyositis (PMS) and dermatomyositis (DMS) shows overall positive results.⁸⁸ However, despite the frequent use of MTX in the inflammatory myopathies, a recent Cochrane database review reveals a paucity of well-designed trials.⁸⁹

Other Rheumatic Diseases. MTX has been used in systemic sclerosis. One RCT looking at MTX use in early systemic sclerosis⁹⁰ showed a trend in benefit for skin scores and pulmonary diffusion capacity and a significant benefit for physician global assessment; a second RCT in established systemic sclerosis⁹¹ showed significant benefit for skin scores and total creatinine clearance. In addition, prospective trials have shown that MTX is efficacious in the treatment of corticosteroid-resistant multisystem sarcoidosis,^{92,93} and a recent RCT showed that if initiated early in sarcoidosis, MTX is an effective steroid-sparing agent.⁹⁴ MTX has also been shown to be effective as primary treatment and as a corticosteroid-sparing agent in inflammatory ocular disease.^{95,96} Finally, MTX in combination with corticosteroids is effective in the treatment of multicentric reticulohistiocytosis.⁹⁷

Dose and Drug Administration

MTX is available as 2.5, 5, 7.5, 10, and 15 mg tablets, and as a solution of 25 mg/mL for subcutaneous or intramuscular

injection. The starting dose is usually 5 to 10 mg given as a single weekly dose. More frequent administration is associated with a significantly increased risk of liver toxicity.⁹⁸ If the oral dose of MTX exceeds 15 mg, consideration should be given to splitting the dose, with each half given 6 to 12 hours apart, for improved bioavailability. The dosage of MTX can be escalated, usually every 4 to 8 weeks to 25 mg/wk to achieve the desired clinical response. MTX may be administered orally via tablet or parenteral solution; the latter is less costly. Because its bioavailability is variable and appears to decrease at higher doses, parenteral MTX is generally recommended if patients have active disease despite oral doses of approximately 20 mg/wk. Recent data have shown that parenteral MTX is clinically superior to orally administered MTX, and that this may be a preferred route of administration, especially if oral MTX is not optimally effective.⁵⁰

Concomitant administration of folic acid (1 to 3 mg/day) decreases the frequency of toxicities, including mucositis, nausea, hematologic abnormalities, and liver enzyme elevations, without seeming to interfere with clinical efficacy.^{99,100} Folic acid administration also decreases hyperhomocysteinemia in patients on MTX, and this may be important to help decrease the already high cardiovascular risk of patients with RA. Low-dose folinic acid has also been used and can markedly reduce MTX toxicity in rheumatic disease therapy without interfering with efficacy if given in doses of 2.5 to 5 mg/wk and if not administered until 24 hours after the MTX dose. Because folic acid is widely available and less expensive, it is preferred by most.

Measurement of MTX-PG levels is commercially available (MTXGlu_n). It would be valuable to have a marker to predict response and adverse events associated with MTX therapy, but mixed results have been obtained in the search for a trend in the dose-response relationship for MTXGlu_n levels and RA disease activity. A recent study showed no relationship between MTXGlu_n concentration and reduced disease activity in RA.¹⁰¹ Furthermore, no relationship was identified between MTXGlu_n levels and adverse events. Disease activity was influenced by red blood cell (RBC) folate level, and further study is warranted to determine whether this may serve as a marker for MTX efficacy.

Geriatric Patients

Patients older than 65 years represent a special subset of patients receiving pharmacotherapy. Pharmacokinetic profiles, including drug distribution, are changed in the elderly as the result of decreases in end-organ blood flow and lean body mass, decreased hepatic drug metabolism, and decreased renal drug excretion. Furthermore, these patients are more likely to have multiple comorbidities, polypharmacy, noncompliance, increased risk for dosage errors, and limited access to medication for financial reasons.¹⁰²

In practice, recommended doses should be reduced when therapy is initiated and should be adjusted for renal function based on creatinine clearance (CrCl).¹⁰³ The serum creatinine may be a misleading measure of renal function in older patients owing to an overall reduction in lean muscle mass. Dosing recommendations are as follows: Initial doses should be around 5 to 7.5 mg/wk and should not exceed 20 mg/wk. Dosage adjustments for CrCl are as follows: For a CrCl of 61 to 80 mL/min, reduce the dose by 25%; for a CrCl of 51 to 60 mL/min, reduce the dose by 30%; for a CrCl of 10 to 50 mL/min, reduce the dose by 50% to 80%; and for a CrCl less than 10 mL/min, avoid use¹⁰⁴ (Table 61-1).

Pediatric Patients (See Table 61-1)

MTX is commonly used in the pediatric population. It can be given orally or subcutaneously, with a starting dose of 0.3 to 1 mg/kg/dose once weekly. It is common to start at 0.3 mg/kg/dose and escalate to a dose of 25 mg/wk. It is suggested that at doses greater than 15 mg/wk, parenteral application should be considered because of better bioavailability and tolerability. Toxicity monitoring is similar to adult recommendations.

Toxicity

Despite initial concerns, when given once a week in doses used for rheumatic diseases and monitored correctly, MTX is very well tolerated. Some of the toxicities of MTX (stomatitis, nausea, bone marrow depression) are dose

Table 61-1 Special Considerations

	Fertility	Pregnancy	Lactation	Elderly	Pediatrics
Methotrexate	W: no effect M: reversible sterility Stop 3 mo before conception	Contraindicated FDA category X; abortifacient; teratogenic	Contraindicated; present in breast milk	Lower initial dose (5-7.5 mg/wk); dose based on CrCl	Dosing based on weight
Leflunomide	No effect; test levels before conception; may require washout	Contraindicated FDA category X; embryolethal; teratogenic	Contraindicated; unknown concentrations in breast milk	No dosage adjustment required	Dosing based on weight
Sulfasalazine	W: no effect M: reversible sterility	Relatively safe; FDA category B, C	Relatively safe; present in breast milk	No dosage adjustment required	Dosing based on weight
Hydroxychloroquine	No effect	Relatively safe; FDA category C	Relatively safe; present in breast milk	No dosage adjustment required	Dosing based on weight

CrCl, Creatinine clearance; FDA, U.S. Food and Drug Administration; M, men; W, women.

dependent, appear to be related to folate deficiency, and respond to folate replacement. Other toxicities appear to be idiosyncratic or allergic and in most cases require discontinuation of MTX (e.g., pneumonitis). Still other toxicities, such as liver fibrosis and cirrhosis, appear to be multifactorial and may depend on the presence of concomitant risk factors, total dose, and frequency of administration.

Gastrointestinal and Hepatic Side Effects

Gastrointestinal symptoms, including dyspepsia, nausea, and anorexia, are common, occurring in up to 20% to 70% of patients within the first year of therapy.¹⁰⁵ These symptoms may be attenuated by adding folic acid or by changing to a parenteral dosing regimen.

The risk of significant liver toxicity appears to be low when MTX is given once weekly to patients who abstain from alcohol consumption and are monitored carefully, and is on the order of 1 case per 1000 after 5 years of use.¹⁰⁶ However, a recent review of a large North American database of patients with RA and PsA found that elevations in aspartate aminotransferase (AST)/alanine aminotransferase (ALT) greater than 1 times the upper limit of normal ($1 \times \text{ULN}$) occurred in 22% and 31% of patients taking MTX or MTX and leflunomide. Elevations greater than $2 \times \text{ULN}$ occurred in 1% to 2% on monotherapy and in greater than 5% on combination therapy. Elevated liver function tests (LFTs) were more likely in patients with PsA.¹⁰⁷ Alcohol consumption, α_1 -antitrypsin deficiency, morbid obesity, diabetes, concomitant hepatotoxic drugs, and chronic hepatitis B or C have all been implicated as possible risk factors for MTX toxicity.¹⁰⁸

Hematologic Side Effects

Bone marrow toxicity, in most cases, is dose dependent and responds to folic acid administration. Pancytopenia, leukopenia, anemia, and thrombocytopenia can occur, but are rare. In a review by Gutierrez-Urena and associates, clinically significant pancytopenia was found to develop in up to 1% to 2% of RA patients on MTX therapy.¹⁰⁹ Severe, life-threatening bone marrow toxicity can be treated with folinic acid (leucovorin) and, if necessary, granulocyte-stimulating factor (G-CSF). Because the elimination of MTX is dependent on the kidney, decreases in renal function may precipitate bone marrow toxicity in patients who have been previously stable. Additional risk factors include hypoalbuminemia, dosing errors, and concomitant use of probenecid or trimethoprim/sulfamethoxazole (TMP/SMX).

Pulmonary Side Effects

Five clinical pulmonary syndromes have been associated with MTX treatment: acute interstitial pneumonitis (hypersensitivity pneumonitis), interstitial fibrosis, noncardiogenic pulmonary edema (seen in high-dose treatment for malignancy with rare reports in RA), pleuritis and pleural effusions, and pulmonary nodules.¹¹⁰ Time lapse from initiation of therapy to cumulative dose before the onset of pulmonary toxicity is extremely variable, at 1 to 480 weeks and 7.5 to 3600 mg of MTX, respectively.¹¹⁰ MTX-induced pulmonary disease is rare and is difficult to quantify, but

estimates suggest an incidence of 3.9 cases per 100 patient-years of MTX exposure and a prevalence of 2.1% to 5.5%.^{111,112}

Patients generally present with shortness of breath, tachypnea, dry cough, and fever. Chest radiographs most typically show a bilateral interstitial infiltrate (although this varies). Infectious causes, including opportunistic organisms, must always be ruled out. If routine evaluations for infection, including sputum studies, and for other medical conditions to explain the pulmonary symptoms are negative, bronchoscopy with bronchoalveolar lavage and transbronchial biopsy is recommended. If MTX pulmonary toxicity is suspected, MTX should be discontinued and supportive treatment initiated with the use of corticosteroids in more severe cases. Some patients with pulmonary toxicity have been successfully restarted on MTX,¹¹³ but clinicians have reported mortality in up to 50% of retreated patients.⁵⁵

Factors that appear to predispose to MTX lung toxicity include age, blue collar occupation, smoking (in women), diabetes, pleuropulmonary rheumatoid disease, and skin rashes from MTX.¹¹⁴

Mucocutaneous Side Effects

The mucocutaneous toxicities of MTX, which have been reported to occur in up to one-third of patients, are dose dependent and respond to folate replacement. Patients generally report fairly minor oral ulcerations, but severe ulceration of the mouth, esophagus, bowel, and vagina can occur, especially at higher doses.

Malignancies

The induction of malignancies by MTX is a concern, and several studies have examined this question with conflicting conclusions. Recently, reports of lymphoma in MTX-treated RA patients have appeared. Because the incidence of lymphoma is increased in RA patients anyway,¹¹⁵ these reports are difficult to interpret. The case for a causative role of MTX has been strengthened, however, because a number of these cases have been B cell lymphomas of the type commonly seen in association with immunosuppression (associated with Epstein-Barr virus) and that may regress after discontinuation of MTX.^{116,117} Subsequently, lack of a causal relationship between MTX treatment and the development of lymphoma has been seen in two large series of RA patients—one prospective study¹¹⁵ and one retrospective study.¹¹⁸ The potential benefits of MTX for most RA patients thus far outweigh these statistically small risks.¹¹⁹

Miscellaneous

Methotrexate Flu. Patients taking MTX may describe flu-like symptoms shortly after taking their weekly dose. Nausea, low-grade fevers, myalgias, and chills are the most common signs of the so-called methotrexate flu. These side effects usually respond to supplementation with folic acid, decreasing the dose, switching from oral to parenteral administration, or changing the time of the dose (so the patient takes MTX right before going to bed).

Nodulosis. The development of, or increase in, the number or size of rheumatoid nodules has been reported to occur in RA patients treated with MTX with a prevalence of up to 8%.¹²⁰ This may occur in rheumatoid factor-negative patients and in those in whom the synovitis is under excellent control. The mechanism of this nodule formation has been suggested to be due to an increase in adenosine, which appears to promote nodule formation.¹²¹ Conversely, nodules have been reported to decrease during MTX therapy.

Vasculitis. Despite efficacy in the treatment of the cutaneous vasculitis associated with RA, leukocytoclastic vasculitis has also been attributed to MTX therapy.¹²²

Fertility, Pregnancy, and Lactation

MTX does not seem to adversely affect female fertility but can cause reversible sterility in men.¹²³ Women and men should discontinue MTX for at least 3 months before attempting to conceive, because of its large distribution and long half-life in the liver. Folic acid supplementation is essential before conception. MTX is included in U.S. Food and Drug Administration (FDA) Pregnancy Category X and is contraindicated in pregnancy. Women of childbearing age who are considered for MTX therapy should receive extensive counseling regarding teratogenic risk and should be placed and maintained on adequate contraception, before therapy is begun. Toxicities include fetal abnormalities such as “aminopterin syndrome” (multiple craniofacial, limb, and central nervous system abnormalities) and embryonic or fetal loss, and MTX at high doses (1 mg/kg) is an effective abortifacient. MTX is also contraindicated during lactation because small amounts are excreted in breast milk (see Table 61-1).

Toxicity Monitoring

The American College of Rheumatology (ACR) has recently revised recommendations for the use of DMARDs, and these serve as an excellent resource.¹²⁴ Toxicities that require monitoring include myelosuppression, hepatotoxicity, and pulmonary toxicity. Baseline evaluation should include a complete blood count (CBC) with platelets, hepatitis B and C serology in high-risk patients, liver transaminases, and creatinine. Although these guidelines make no recommendations on the need for a baseline chest x-ray (CXR), this is a reasonable approach. Liver biopsies are not routinely recommended before MTX is initiated. The rare patients whom one wants to treat with MTX despite abnormalities in screening laboratory or other significant risk factors may require liver biopsy before MTX is initiated. In addition, biopsies are recommended only in those patients who continue to have enzyme abnormalities, and for whom continuation of MTX therapy is contemplated.

Monitoring for toxicity should be done every 2 to 12 weeks and is based on the duration of therapy, with more frequent monitoring provided earlier in the course of treatment. Systems review and physical examination should include monitoring for symptoms or signs of myelosuppression (fever, infection, bruising, and bleeding), pulmonary toxicity (shortness of breath, cough, rales), gastrointestinal intolerance (nausea, vomiting, diarrhea), and lymphadenopathy. Laboratory parameters that should be followed include a CBC with platelets, liver transaminases, and creatinine (Table 61-2).

It is important to consider vaccination status in any patient who is going to use MTX. RA patients have an increased incidence of death from pneumonia,¹²⁵ and MTX may reduce the immune response to pneumococcal

Table 61-2 Safety Monitoring

	Baseline	<3 Months of Drug Therapy*	Monitoring Interval 3-6 Months of Drug Therapy*	>6 Months of Drug Therapy*	Contraindications
MTX	CBC, LFT, Cr, HBV, HCV; vaccinate: influenza, <i>Pneumococcus</i> , HBV	Every 2-4 wk	Every 8-12 wk	Every 8-12 weeks	Active infection, symptomatic pulmonary disease, WBC <3000/mm ³ , Plt <50,000/mL ³ , CrCl <30 mL/min, history of myelodysplasia or recent lymphoproliferative disorder, LFT >2 × ULN, acute or chronic HBV or HCV, pregnancy, lactation
Leflunomide	CBC, LFT, Cr, HBV, HCV; vaccinate: influenza, <i>Pneumococcus</i> , HBV	Every 2-4 wk	Every 8-12 wk	Every 8-12 wk	Active infection, WBC <3000/mm ³ , Plt <50,000/mL ³ , history of myelodysplasia or recent lymphoproliferative disorder, LFT >2 × ULN, acute or chronic HBV or HCV, pregnancy, lactation
Sulfasalazine	CBC, LFT, Cr; vaccinate: influenza, <i>Pneumococcus</i>	Every 2-4 wk	Every 8-12 wk	Every 8-12 wk	Sulfa allergy, Plt <50,000/mL ³ , LFT >2 × ULN, acute HBV/HCV, some classes of chronic HBV/HCV

antigen.¹²⁶ Thus, any patient in whom MTX is going to be used should first receive the pneumococcal vaccination, with booster as appropriate. Vaccinations for hepatitis B virus for at-risk patients and yearly influenza vaccines are recommended as well. Caution should be exercised when administering live virus vaccinations to patients on MTX.

Drug Interactions and Contraindications

Drug Interactions

Drugs that are known hepatotoxins, such as sulfasalazine, leflunomide, and azathioprine, may potentiate liver toxicity when used in combination. Organic acids such as sulfonamides, salicylates, NSAIDs, penicillin G, piperacillin, and probenecid competitively inhibit tubular secretion, and this delays MTX clearance.¹²⁷ MTX also undergoes distal tubular reabsorption, which may be enhanced by the addition of HCQ¹²⁸ and blocked by the addition of folic acid.¹²⁷ Drugs that affect renal function should be used with caution because of the renal clearance of MTX and, therefore, the increased risk of MTX toxicity that could occur because of decreased clearance.

Several of the aforementioned drugs deserve special mention. Trimethoprim-sulfamethoxazole should be avoided or used with extreme caution because of possible hematologic toxicity with MTX. Mechanisms for this toxicity include an additive antifolate effect from trimethoprim, decreased MTX clearance due to inhibition of tubular secretion by sulfamethoxazole, and altered MTX plasma protein binding. NSAIDs are commonly used in RA patients as adjunctive therapy. NSAIDs may increase MTX levels by displacing MTX from plasma proteins and limiting tubular secretion. Despite lack of a significant pharmacokinetic or clinical interaction between low-dose MTX and a variety of NSAIDs,¹²⁹ vigilance for MTX toxicity should increase whenever NSAID dosages are changed in patients on stable weekly doses of MTX. Low doses of aspirin used for

cardiovascular prophylaxis are not likely to be of concern. Furthermore, probenecid should be avoided because it inhibits tubular secretion of MTX.

Contraindications

MTX should not be used in severe renal, pulmonary, or hepatic impairment, pre-existing bone marrow suppression, alcoholic liver disease, and pregnancy or breastfeeding. Ongoing or active infection is also a contraindication. In most cases, patients who desire to continue drinking alcohol should not be treated with MTX. Mild to moderate renal insufficiency is a relative contraindication, and use of MTX in these patients may require more vigilant toxicity monitoring (Table 61-3).

LEFLUNOMIDE

KEY POINTS

Leflunomide reversibly inhibits dihydroorotate dehydrogenase (DHODH).

Loading doses often are not used in clinical practice because of gastrointestinal toxicity.

Because of enterohepatic recirculation, leflunomide has a very long half-life.

Leflunomide is absolutely contraindicated in pregnancy, and levels must be checked with a washout protocol if needed before conception.

Vigilance must be used for hepatotoxicity.

Leflunomide, an isoxazole derivative, is a synthetic DMARD approved for the treatment of RA. It emerged from a specific anti-inflammatory drug development program and has potent immunomodulatory effects.

Figure 61-4 Leflunomide is rapidly and completely metabolized to its active metabolite, A77 1726.

Chemical Structure

Leflunomide is a low-molecular-weight isoxazole compound and is chemically unrelated to any previous immunosuppressant. Leflunomide is a pro-drug and is rapidly and completely converted to its active metabolite, the

malononitriloamide A77 1726. A77 1726 is also known as teriflunomide (Figure 61-4).

Actions of Leflunomide

As with MTX, the precise mechanism of action responsible for the effects of leflunomide in rheumatic disease is not completely understood.¹³⁰ Leflunomide is immunomodulatory, with the net effect being a reduction in activated T lymphocytes. Its two *in vitro* mechanisms of action vary depending on concentration: (1) At the concentration of the active metabolite (A77 1726) achieved in patients, its major effect appears to be reversible inhibition of the enzyme dihydroorotate dehydrogenase (DHODH), which results in inhibition of pyrimidine synthesis; (2) at higher concentrations, A77 1726 also inhibits tyrosine kinases, interfering with cell signal transduction.¹³¹

Activation of T cells results in progression from the resting phase (G_0) to the G_1 phase, where ribonucleotides are synthesized, and then to the S phase, where cellular DNA is replicated in preparation for mitosis. T cell activation requires significant increases in *de novo* pyrimidine and purine biosynthesis. Sensors such as proto-oncogenes (*p53*) and checkpoints (cyclins C and D) in this pathway monitor the level of nucleotide pools and prevent damaged cells from replicating.¹³¹

Uridine monophosphate (rUMP) is a precursor for the formation of pyrimidine nucleotides and thus is essential for both RNA and DNA synthesis. The steps in *de novo* rUMP synthesis are seen in Figure 61-5. A critical step in this pathway is the generation of dihydroorotate in the

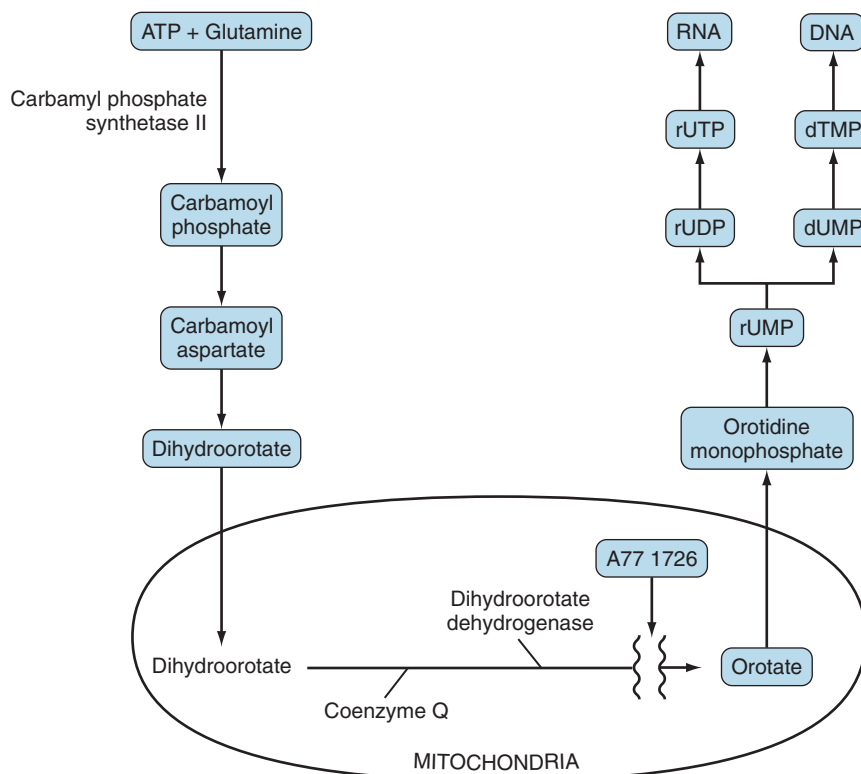

Figure 61-5 The active metabolite of leflunomide, A77 1726, blocks the conversion of dihydroorotate to orotate within the mitochondria. ATP, adenosine triphosphate; DNA, deoxyribonucleic acid; RNA, ribonucleic acid; rUMP, uridine monophosphate.

cytoplasm with subsequent diffusion into the mitochondria, where the enzyme dihydroorotate dehydrogenase (DHODH) is located. DHODH converts dihydroorotate to orotate, and the latter diffuses back into the cytoplasm and is subsequently converted to rUMP and ultimately to RNA and DNA.

The first postulated mechanism of action of leflunomide consists of inhibition of DHODH by A77 1726, which lowers orotate levels and leads to a decrease in rUMP and subsequent nucleotide synthesis, resulting in T cell cycle arrest. This mechanism of action has been substantiated by experimental evidence. In vitro mitogen-stimulated activation of T cells is blocked by levels of A77 1726 that inhibit DHODH, and this inhibition can be reversed by the addition of uridine, suggesting that A77 1726 works by disruption of pyrimidine biosynthesis.^{132,133} Further, the only enzyme inhibited by A77 1726 in this pathway, at concentration obtained in vivo, is DHODH.¹³⁴

Evidence also exists to support that inhibition of DHODH produces an arrest of lymphocytes in the G₁ phase of the cell cycle.¹³⁵ If the level of ribonucleotides, including rUMP, falls below a critical point, cytoplasmic p53 activation occurs, and p53 will translocate to the nucleus and initiate cellular arrest by ultimately preventing transcription of cyclins D and E. In cultures of human T cells, A77 1726 depletes rUMP pools and results in an accumulation of nuclear p53 with resultant cell cycle arrest.¹³⁶ In comparison, treatment of cell lines lacking p53 with A77 1726 does not cause a G₁ phase arrest.¹³⁷

Resting lymphocytes maintain ribonucleotide requirements largely through salvage pathways and are essentially unaffected by leflunomide.¹³⁸ Active, or autoimmune, lymphocytes rely on the de novo pathway and are affected by leflunomide. Over the course of treatment with this slow-acting agent, autoimmune lymphocytes should be removed progressively.¹³¹

At higher concentrations, A77 1726 inhibits phosphorylation of tyrosine kinases that are critical for cell growth and differentiation of activated cells.^{139,140} This inhibition has been proposed to partially or completely explain the antiproliferative effects of leflunomide; however, it is unclear whether concentrations sufficient to achieve this effect are obtained in vivo.

Several other additional anti-inflammatory properties of leflunomide have been noted. Leflunomide has the ability to block the activation of nuclear factor κ B (NF κ B),¹⁴¹ which regulates the expression of genes important in inflammatory processes, including those seen in inflammatory arthritis.¹⁴² Ex vivo and in vitro studies in humans have shown that both leflunomide and MTX inhibit neutrophil chemotaxis, which may decrease the recruitment of inflammatory cells into the joints.⁴⁴ Leflunomide has also been shown to decrease the ratio of MMP-1 to TIMP-1.⁴⁴ Finally, leflunomide alters the synthesis of cytokines by augmenting the immunosuppressive cytokine-transforming growth factor- β 1 and suppressing the immunostimulatory cytokine IL-2.¹⁴³

Pharmacology

Absorption and Bioavailability

The gastrointestinal tract and the liver rapidly and completely convert ingested leflunomide into A77 1726. Food

does not interfere with absorption. Circulating A77 1726 is highly bound (more than 99%) to plasma proteins, predominantly albumin. Its plasma concentration is linearly correlated with a single oral dose over a range of 5 to 25 mg; steady state is reached in 7 weeks after daily dosing.¹⁴⁴

Distribution and Half-Life

A77 1726 has a half-life of approximately 2 weeks (mean, 15.5 days),¹⁴⁴ with a low apparent volume of distribution. A77 1726 undergoes enterohepatic recirculation. In healthy subjects, 90% of leflunomide is excreted by 28 days,¹⁴⁴ but some may be present for much longer periods.

Elimination

In healthy subjects, the proportions excreted by the kidney and the gut are nearly equal. Because detectable A77 1726 may be present in the body months or years later, the ability to rapidly and effectively eliminate A77 1726 with cholestyramine is important. Oral administration of cholestyramine 8 g three times daily can lower the apparent half-life of A77 1726 to 1 to 2 days.¹⁴⁵ Furthermore, activated charcoal 50 g every 6 hours can reduce plasma levels by 50% within 24 hours.¹⁴⁵

Indications

Rheumatoid Arthritis. Leflunomide was first shown to be safe and effective in treating RA in a placebo-controlled, dose-ranging, 6-month trial.¹⁴⁴ Two pivotal trials, one in Europe and one in the United States, have compared leflunomide with sulfasalazine (SSZ) and MTX. The European trial had three arms: leflunomide (20 mg/day after a loading dose), sulfasalazine (escalated to 2 g/day), and placebo.¹⁴⁶ In this trial, both leflunomide and sulfasalazine were superior to placebo in terms of swollen and tender joint counts, as well as physicians' and patients' overall assessments. It is important to note that both the leflunomide and sulfasalazine groups reported significant effects on slowing radiographic progression of disease compared with placebo. The U.S. trial compared patients treated with leflunomide (20 mg/day after a loading dose), MTX (7.5 to 15 mg/wk), or placebo.¹⁴⁷ Again, both active drugs were found to be superior to placebo but not different from each other. Both leflunomide and MTX also slowed radiographic progression of disease compared with the placebo group. Another trial compared leflunomide (20 mg/day with loading) with MTX (10 to 15 mg/wk) in a 1-year trial with a 1-year extension.¹⁴⁸ In this trial, MTX was shown to be statistically superior to leflunomide for the clinical outcomes measured, as well as the rate of radiographic progression after 2 years.

Other Rheumatic Diseases. Leflunomide has been reported to be efficacious in systemic lupus erythematosus. In a randomized, controlled trial, leflunomide was more effective than placebo in improving markers of lupus disease activity, and was safe and well tolerated.¹⁴⁹ A subsequent small, prospective, open-label trial of patients with lupus nephritis unresponsive to conventional therapy showed that leflunomide was efficacious and well tolerated.¹⁵⁰

Leflunomide has been shown to be effective in treating psoriatic arthritis and psoriasis when compared with placebo.¹⁵¹ In an open-label trial of ankylosing spondylitis, leflunomide was shown to be effective in treating peripheral arthritis, but axial symptoms did not improve.¹⁵²

Both an open-label trial¹⁵³ and a randomized, controlled clinical trial¹⁵⁴ have shown the efficacy of leflunomide in maintaining remission in granulomatosis with polyangiitis after successful induction with cyclophosphamide. In the latter trial, leflunomide was superior to methotrexate in preventing relapse.

Leflunomide has also been shown to be safe and effective in patients with juvenile idiopathic arthritis (JIA) who did not respond to or could not tolerate MTX.¹⁵⁵

Dose and Drug Administration

Leflunomide is available in oral tablets at doses of 10, 20, and 100 mg. Oral leflunomide is rapidly metabolized to A77 1726, which has a very long half-life; therefore, the standard recommendation is to start therapy with a loading dose of 100 mg daily for 3 days, then switch to the standard maintenance dose of 20 mg daily. Despite this recommendation, many clinicians no longer prescribe a loading dose because it is believed to increase the drug's gastrointestinal toxicity.¹⁵⁶ Also, it is common practice to decrease the dose to 10 mg daily if toxicity occurs, or if complete control of the disease can be maintained. Because of its long half-life, some clinicians give leflunomide less often (three to five times per week).

Geriatric Patients (See Table 61-1)

No pharmacokinetic studies specific to geriatric patients have been done for leflunomide; hence, dosing recommendations are the same as for the general population. No clinical experience in patients with renal insufficiency has been reported, so those patients should be monitored carefully.

Pediatric Patients (See Table 61-1)

Although not approved in the United States to treat patients with JIA, leflunomide is used off-label for this condition at a dose of 10 to 20 mg/day. This dosing is often based on a patient's body weight. A recently published example of dosing by body weight is as follows: A patient weighing less than 20 kg receives 10 mg every other day, a patient weighing more than 20 kg but less than 40 kg receives 10 mg/day, and a patient weighing more than 40 kg receives 20 mg/day.¹⁵⁷

Toxicity

For major controlled trials that have used leflunomide at a dose of 20 mg/day, the incidence of adverse events that resulted in trial withdrawal are shown in Table 61-4. Leflunomide-associated withdrawals (19%) were more frequent than those associated with MTX (14%), were similar in frequency to those associated with sulfasalazine (19%), but were more frequent than those associated with placebo treatment (8%).

Table 61-4 Leflunomide Trial Withdrawals for Adverse Events

	No. of Patients	Withdrawals
Leflunomide	816	154 (19%)
Methotrexate	680	94 (14%)
Sulfasalazine	133	25 (19%)
Placebo	210	16 (8%)

Gastrointestinal and Hepatic Side Effects

The most common side effect that limits the use of leflunomide is diarrhea, which responds to dose reduction and may be less common if the loading dose is not used. Abdominal pain, dyspepsia, and nausea from leflunomide appear to be slightly increased over placebo rates.

Liver toxicity can occur in association with leflunomide administration. Data from a large U.S. cohort of RA and PsA patients show that elevations in ALT/AST levels greater than 1 times the upper limit of normal ($1 \times \text{ULN}$) occurred in 17% and elevations greater than $2 \times \text{ULN}$ occurred in 1% to 2% of patients taking leflunomide. Leflunomide given in combination with MTX resulted in ALT/AST elevations greater than $1 \times \text{ULN}$ in 31% and greater than $2 \times \text{ULN}$ in 5% of patients. Furthermore, this change in transaminases was more commonly seen in PsA patients.¹⁰⁷ The European Agency for Evaluation of Medicinal Products (EMA) reported 296 patients with hepatic abnormalities and 15 patients with liver failure and death while taking leflunomide.^{158,159} The U.S. Food and Drug Administration (FDA) reviewed adverse event reports between August 2002, and May 2009, and found 49 cases of severe liver injury, 14 of which resulted in death.¹⁶⁰ Most patients with hepatotoxicity have risk factors, including concomitant administration of another hepatotoxic agent or underlying liver disease.

Cardiovascular Side Effects

Hypertension has consistently been reported to occur more frequently in leflunomide-treated compared with placebo-treated patients.^{146,147} Additionally, elevation of cholesterol levels has been reported in association with leflunomide use.¹⁶¹ Both of these effects should be monitored because of the excess cardiovascular mortality reported in patients with RA.

Miscellaneous

Dermatologic. Skin rashes have been reported, most commonly occurring between the second and fifth months and necessitating discontinuation of the drug. Severe skin reactions such as Stevens-Johnson syndrome or toxic epidermal necrolysis require leflunomide washout with cholestyramine.

An increased incidence of alopecia has been reported in clinical trials in association with leflunomide.

Pulmonary. Rare postmarketing reports have described interstitial lung disease, including interstitial pneumonitis and pulmonary fibrosis.

Hematologic. Rare cases of pancytopenia have been reported in postmarketing surveillance, primarily in patients

with known risk factors for blood dyscrasias. An increased risk of lymphoproliferative disorders has not been associated with leflunomide.

Weight Loss. Significant weight loss has also been reported to occur in patients taking leflunomide.¹⁶²

Fertility, Pregnancy, and Lactation

Leflunomide is rated Pregnancy Category X. Animal studies have demonstrated substantial teratogenic and embryolethal effects with small doses of leflunomide. Therefore, women of childbearing potential should be strongly counseled about this, and leflunomide should not be prescribed for women who are not practicing reliable birth control methods. A pregnancy test should be considered before therapy is initiated. Leflunomide excretion in milk is unknown; therefore, nursing mothers should not receive leflunomide.

It is critically important to note that the active metabolite of leflunomide (A77 1726), largely because of its enterohepatic circulation, may remain in the body for years. Therefore, if a woman who has previously received leflunomide wishes to become pregnant, A77 1726 levels should be measured. Active elimination of leflunomide from the body should be considered for levels above 0.02 mg/L. This can be achieved by the oral administration of cholestyramine for 11 days (8 g three times daily).¹⁶³ Before pregnancy is attempted, verification of levels below 0.02 mg/L should be confirmed on two separate occasions, at least 14 days apart, and women should then wait an additional three full menstrual cycles.¹⁶⁴ Patients may require more than one course of cholestyramine to achieve this level. Although no data exist, men wishing to father children should undergo the same washout procedure as women and should wait an additional 3 months after the second drug plasma level is verified below 0.02 mg/L (see Table 61-1).

Toxicity Monitoring

Similar to MTX, the ACR has published guidelines on the initiation and monitoring of leflunomide.¹²⁴ Patients taking leflunomide should have a baseline CBC and liver enzyme monitoring, including AST, ALT, and albumin. Serum creatinine is important because leflunomide is partially eliminated by the kidney. The frequency of monitoring depends on the duration of therapy (see Table 61-2). More frequent monitoring may be warranted if concomitant immunosuppressive agents, such as MTX, are given. If patients experience significant toxicity, a washout procedure is indicated to more rapidly eliminate the drug. Caution should be exercised when live virus vaccinations are administered to patients on leflunomide.

Drug Interactions and Contraindications

Drug Interactions

Cholestyramine interferes with enterohepatic recycling of leflunomide, resulting in lower serum concentrations. Concomitant use with hepatotoxic agents, including MTX, increases the risk of liver toxicity, and leflunomide must be used with caution and monitored judiciously. Rifampin may

increase the serum concentration of A77 1726. Leflunomide may potentiate warfarin therapy.

Contraindications

Leflunomide should not be used in patients with impaired liver function, severe renal impairment, bone marrow dysplasia, severe immunodeficiency, severe hypoproteinemia, or known hypersensitivity to the drug. The liver is involved in enterohepatic recirculation and biliary excretion, thus leflunomide use in liver disease is contraindicated. In renal insufficiency, the levels of circulating A77 1726 do not appear to be increased, but the component of free A77 1726 is increased. Leflunomide is contraindicated in the setting of serious infection and should be discontinued in patients with new or worsening pulmonary symptoms or rash. Leflunomide is absolutely contraindicated in pregnancy and breastfeeding (see Table 61-1).

SULFASALAZINE

KEY POINTS

Sulfasalazine (SSZ) has antimicrobial and anti-inflammatory properties, but the exact mechanism of action is unknown.

SSZ is commonly used as part of combination therapy for RA.

Gastrointestinal intolerance is a common side effect.

Although rare, surveillance for leukopenia is important early in the course of the treatment.

Sulfasalazine (SSZ) was the first agent to be synthesized specifically for rheumatoid arthritis in 1938, by Professor Nanna Svartz of Stockholm, in collaboration with the Swedish pharmaceutical company Pharmacia. The prevailing notion at that time was that RA was caused by infection, and SSZ was designed with both anti-inflammatory and antibacterial properties.

Chemical Structure

Salicylazosulfapyridine (SASP), now known as sulfasalazine, is a conjugate of the anti-inflammatory 5-aminosalicylic acid (5-ASA or mesalamine) and the antibacterial sulfapyridine joined by an azo bond (Figure 61-6). The abbreviation SASP is still in use as an alternative to SSZ.

Actions of Sulfasalazine

Despite more than seven decades of use, the mechanism of action of SSZ in rheumatic disease still is not fully elucidated. When SSZ was designed, its antimicrobial properties were thought to be fundamentally important in successful treatment of RA, which was postulated to be an enteropathic arthropathy. Through alteration of gut flora, SSZ may downregulate the immune response leading to inflammatory arthritis. Although this hypothesis has never been disproved, this mechanism of action has fallen out of favor for several reasons: To date, no conclusive evidence has been found for an infectious cause of RA, other

Figure 61-6 Sulfasalazine and its major metabolites.

sulfonamides have failed to result in clinical improvement, and a relationship between gut flora and clinical response to SSZ is lacking.¹⁶⁵ Currently, SSZ is presumed to work via anti-inflammatory and immunomodulatory effects.

SSZ has been demonstrated *in vitro* to possess multiple anti-inflammatory properties. First, SSZ weakly inhibits the proinflammatory effects of the arachidonic acid cascade, with a slight inhibitory effect on prostaglandin E₂ synthetase activity,¹⁶⁶ as well as lipoxygenase products.¹⁶⁷ SSZ also downregulates neutrophil chemotaxis, migration, and proteolytic enzyme production and degranulation,^{168,169} and has been shown to inhibit neutrophil activation by decreasing the flux of second messengers involved in intracellular signal transduction.¹⁷⁰ Neutrophil migration to sites of inflammation can be downregulated by adenosine. It has been shown that SSZ inhibits folate-dependent enzymes, including ATIC and DHFR, resulting in increased adenosine release into the extracellular milieu.¹⁷¹ Gadangi and colleagues confirmed that SSZ, like MTX, modulates inflammation via increased adenosine release.¹⁷² This effect appears to be due solely to SSZ as sulfapyridine and 5-ASA are inactive. SSZ is a more potent inhibitor of ATIC than is MTX.

SSZ also has been shown to possess multiple immunomodulatory properties. *In vitro*, SSZ inhibits T cell proliferation, natural killer cell activity, and B cell activation, with resultant declines in immunoglobulin synthesis and RF production.¹⁶⁵ In all of these systems, sulfapyridine and 5-ASA are less active than SSZ. Cytokine profiles are also altered by SSZ, resulting in inhibition of the T cell cytokines IL-2¹⁷³ and γ -interferon,¹⁷⁴ and the monocyte/macrophage cytokines IL-1, TNF, and IL-6.^{175,176} NF κ B is a key transcription factor that when active mediates the transcription of key cytokines, adhesion molecules, and chemokines essential to mounting an immune response. *In vitro*, SSZ, but not sulfapyridine or 5-ASA, inhibits NF κ B translocation to the nucleus.¹⁷⁷

SSZ more so than sulfapyridine inhibits endothelial cell proliferation and angiogenesis, which likely contributes to the synovitis of RA.¹⁷⁸ The synovial fibroblast also plays a

key role in the pathogenesis of RA, and SSZ inhibits fibroblast proliferation and metalloproteinase synthesis.¹⁷⁹ Finally, SSZ has been shown to inhibit the formation of osteoclasts and may be antiresorptive in RA.¹⁸⁰

The active moiety of SSZ is controversial. The parent compound, SSZ, appears to have the most biologic activity when compared with sulfapyridine and 5-ASA. However, the SSZ levels needed *in vitro* to see the anti-inflammatory and immunomodulatory effects are far greater than those obtained *in vivo*. There has not been a demonstrable relationship shown between plasma SSZ, sulfapyridine, and 5-ASA levels that correlate with clinical efficacy, so serum levels may be irrelevant.¹⁶⁵ In an open, nonrandomized study comparing two groups of patients who received either sulfapyridine or 5-ASA in doses that would represent the molar equivalent of 2 g of SSZ, the group receiving sulfapyridine showed significant improvement in erythrocyte sedimentation rate (ESR) and in some clinical parameters, including grip strength and joint circumference.¹⁸¹ Taken together, it would appear that both SSZ and sulfapyridine have a role in the therapeutic efficacy for RA.

One potential site of action for SSZ that may explain its systemic action despite low serum levels is the mucosa-associated lymphoid tissue (MALT) in the small bowel.¹⁶⁵ In the gut lumen, the therapeutic concentration of SSZ is at least two times greater than in the serum, and drug concentration in the surrounding mucosal tissue is likely also high. The gut immune system is extensive, and active communication with the rest of the body occurs via migration and recirculation of activated lymphocytes.¹⁶⁵ Furthermore, a link between MALT and the joints has been suggested.¹⁸² Evidence that some of the efficacy of SSZ may be mediated via MALT is described as follows: Treatment with SSZ has been shown to decrease circulating immunoglobulin (Ig) A-producing cells and serum levels of IgA, correlating with disease improvement¹⁸³; SSZ has been shown to reduce gut mucosa lymphocytes in treated patients¹⁸⁴; and SSZ has been shown to modulate an immune response elicited by an oral antigen in mice and healthy volunteers.¹⁸⁵

Pharmacology

Absorption and Bioavailability

Less than 30% of SSZ is absorbed by the small bowel; most undergoes enterohepatic circulation and is secreted unchanged in the bile, with a resulting bioavailability of 10%.¹⁶⁵ The steady-state serum concentration of SSZ is 5 μ g/mL after an oral dose of 2 g/day. Most SSZ reaches the colon, where intestinal bacteria reduce the azo bond and release the two active components: sulfapyridine and 5-ASA.¹⁸⁶ Most of the sulfapyridine is absorbed from the colon (>90%) and appears in plasma 4 to 6 hours after an oral dose (steady-state serum concentration of 30 μ g/mL after 2 g/day dose). Most of the 5-ASA (80% to 90%) remains in the bowel.¹⁶⁵ Sulfapyridine and SSZ are likely the active components in rheumatic disease, and 5-ASA is the active component in ulcerative colitis.¹⁸⁷

The bioavailability of standard SSZ is similar to that of enteric-coated SSZ.¹⁸⁸ Administration of SSZ with food decreases the blood concentration of both SSZ and sulfapyridine.¹⁸⁹

Distribution and Half-Life

Both SSZ and sulfapyridine are widely distributed in the body with more than 99% and 50% to 70% plasma protein binding, respectively.^{165,189} Serum and synovial concentrations are comparable.¹⁹⁰ The half-life of SSZ is 6 to 17 hours with upper range values reflecting older patients, and the half-life of sulfapyridine is 8 to 21 hours with upper range values reflecting slow acetylators.¹⁹¹

Elimination

Sulfapyridine is extensively metabolized in the liver by *N*-acetylation and ring hydroxylation with subsequent glucuronidations,¹⁹² and because of genetic variations in acetylator phenotype, wide variability is seen among individuals.¹⁹¹ Slow acetylators have a reduced clearance rate and higher serum sulfapyridine concentrations. Sulfapyridine is excreted in the urine, and 5-ASA is eliminated primarily in the feces. The small portion of 5-ASA that is absorbed is excreted in the urine as *N*-acetylmessalamine.¹⁹³

Indications

Rheumatoid Arthritis. Multiple published trials since the early 1980s have showed significant benefit in both clinical and laboratory parameters for SSZ (2 to 3 g daily) versus placebo in the treatment of RA.¹⁹⁴ A meta-analysis of randomized controlled clinical trials of SSZ for the treatment of RA was published in 1999.¹⁹⁵ In this analysis, SSZ was compared with placebo and other single DMARD therapies, including HCQ, *D*-penicillamine (*D*-Pen), and gold sodium thiomalate or aurothioglucose. In trials looking at SSZ versus placebo, SSZ was shown to be superior to placebo in terms of improvement in multiple clinical parameters. The withdrawal rate due to lack of efficacy was significantly greater in the placebo group than in the SSZ group; however, more patients in the SSZ group than in the placebo group withdrew because of adverse effects ($P < .0001$). No single DMARD emerged as clinically superior in this meta-analysis. Subsequent studies have demonstrated equivalent clinical efficacy with SSZ and MTX,^{196,197} as well as with SSZ and leflunomide,¹⁴⁶ although a 2-year extension trial did show that beneficial effects are sustained to a greater extent with leflunomide than with SSZ.¹⁹⁸

Spondyloarthropathies

Psoriatic Arthritis (PsA). A recently published systematic review of therapies for psoriatic arthritis looked at six randomized controlled trials comparing SSZ with placebo in PsA.¹⁹⁹ Results show that SSZ is efficacious in treating the peripheral arthritis of PsA, but does not appear to influence the axial manifestations.²⁰⁰ Few data on the prevention of radiographic progression are available.

Ankylosing Spondylitis (AS). A recent meta-analysis reviewed 11 trials that included 895 patients with AS treated with SSZ or placebo.²⁰¹ In all patients with AS, SSZ showed some benefit in reducing ESR and easing spinal stiffness. The authors concluded that SSZ may benefit patients at an early disease stage with a higher ESR and peripheral arthritis. This finding is in agreement with those of Clegg and co-workers, who found a significant benefit for

SSZ in peripheral arthritis, but not in axial arthritis, in AS.²⁰⁰

Reactive Arthritis (ReA). Most cases of ReA resolve spontaneously; others become chronic with peripheral or axial arthritis. In a randomized, controlled trial of 134 male veterans with ReA (predominantly peripheral arthritis) unresponsive to NSAIDs, SSZ was more effective than placebo.²⁰²

Inflammatory Bowel-Associated Arthritis. SSZ has been used effectively to treat ulcerative colitis and distal Crohn's disease. No randomized controlled trials have investigated SSZ in terms of peripheral or axial arthritis manifestations of these diseases, although SSZ is used in clinical practice for peripheral arthritis.

Juvenile Inflammatory Arthritis. SSZ has been shown to be effective in polyarticular and pauciarticular juvenile inflammatory arthritis. A literature review by Brooks in 2001 found reports of 550 patients with juvenile inflammatory arthritis (half with polyarticular and one-third with pauciarticular disease) treated with SSZ.²⁰³ Results showed at least some drug-associated benefit in all subtypes, with the best response noted in late-onset pauciarticular disease and the least benefit observed in systemic-onset disease. Toxicity and intolerance were similar to those noted with adult use of SSZ, except for a substantial incidence of serum sickness in patients with systemic-onset disease.

Dosing

SSZ is available in regular and enteric-coated tablets of 500 mg and in a suspension of 50 mg/mL. To minimize side effects, most clinicians will prescribe 500 mg daily and will escalate the dose by 500 mg/day every week to the standard dose of 1500 to 3000 mg divided daily. Dose reduction may ameliorate side effects.

Geriatric Patients (See Table 61-1)

Dosing recommendations for SSZ in geriatric patients are the same as for the general adult population.¹⁰⁴ Studies of pharmacokinetics in the elderly have shown that although the elimination half-life is longer, it is primarily dependent on acetylator phenotype; however, the dose should be reduced for renal insufficiency.¹⁰²

Pediatric Patients (See Table 61-1)

In pediatric patients, SSZ is dosed initially at 10 to 12.5 mg/kg/day, with a weekly dose increase of 50 mg/kg/day in two divided doses, until a maintenance dose of 2 g/day is achieved. This can be escalated to 3 g/day if no response is seen with lower doses.

Toxicity

In general, a majority of adverse effects from SSZ occur within the first several months of treatment and decrease with continued use.²⁰⁴ The most common early adverse effects include gastrointestinal (GI) effects, headache, dizziness, and rash. They tend to decrease with continued use.¹⁸⁹

Gastrointestinal and Hepatic

Nausea and upper abdominal discomfort are the most common adverse effects with SSZ. Nausea frequently occurs with central nervous system (CNS) effects, including dizziness and headache. In one large cohort of 1382 RA patients, GI/CNS effects were reported as transient in 8% of patients; SSZ was continued and in another 18% led to discontinuation of therapy.²⁰⁵ Nausea is more common in patients who achieve higher sulfapyridine levels and in slow acetylators.²⁰⁶ Diarrhea can occur, usually in the first several months. GI effects may be decreased by administration of enteric-coated preparations. Elevations in liver transaminases may occur and are usually transient. However, they may be accompanied by fever, rash, hepatomegaly, and possibly eosinophilia.²⁰⁴

Hematologic

Hematologic disturbances are rare, occurring in less than 3% of patients; they usually occur within the first 3 months.¹⁸⁹ The most common abnormalities include leukopenia that usually reverses upon cessation of the drug, although some cases of fatal agranulocytosis have been reported, warranting continued surveillance.²⁰⁷ Macrocytosis and hemolysis have been reported with SSZ; its use should be avoided in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Folic acid supplementation may be reasonable because of SSZ effects on folate metabolism. Thrombocytopenia is rare.

Dermatologic

Rashes occur in less than 5% of patients, usually in the first 3 months of therapy.²⁰⁵ Rashes are usually maculopapular, pruritic, and generalized, although some patients develop urticaria. Desensitization to SSZ has been reported.²⁰⁸ Anecdotally, erythema multiforme, toxic epidermal necrolysis, and Stevens-Johnson syndrome have been rarely reported, but were not seen in the major clinical trials. Photosensitivity has also been reported. Patients who develop a rash while on SSZ should be cautioned to avoid other sulfonamide-containing agents, such as thiazide diuretics, celecoxib, and antibiotics.

Pulmonary

Pulmonary toxicity from SSZ is rare and manifests as reversible infiltrates with peripheral eosinophilia, cough, dyspnea, fever, and weight loss.²⁰⁹ Pathology reveals an eosinophilic pneumonia with interstitial infiltrates with or without fibrosis. Most cases resolve with discontinuation of SSZ with or without corticosteroids.

Miscellaneous

Minor reactions, such as irritability, anxiety, headache, and difficulty sleeping, may occur.^{204,205} Rare cases of drug-induced lupus,²¹⁰ hypogammaglobulinemia,²¹⁰ and aseptic meningitis have been reported.²¹¹ Advise patients that they may develop orange discoloration of their urine, sweat, and tears.

Fertility, Pregnancy, and Lactation

No reports have described diminished fertility in women taking SSZ; however, men can have oligospermia, impaired sperm motility, and abnormal sperm morphology²¹² that returns to normal 2 to 3 months after cessation of the drug. SSZ is considered FDA Category B, C for pregnancy. SSZ and sulfapyridine cross the placenta, and fetal concentrations are equivalent to maternal concentrations; however, SSZ does not seem to cause or increase fetal abnormalities or spontaneous abortions, and may be one of the DMARDs of first choice for treating rheumatic disease in women of childbearing age who are or wish to become pregnant.¹²³ Sulfapyridine is excreted into breast milk, and one report described a child who developed bloody diarrhea, which led the American Academy of Pediatrics to classify SSZ as a drug that must be given with caution to nursing women¹²³ (see Table 61-1).

Toxicity Monitoring

Most side effects from SSZ occur early in the course of treatment. The ACR guidelines recommend a baseline CBC with platelets, liver enzyme monitoring (including AST, ALT, and albumin), creatinine, and consideration for G6PD.¹²⁴ The frequency of monitoring depends on the duration of therapy (see Table 61-2). Vaccination with *Pneumococcus* should be given if appropriate at the initiation of therapy, and yearly influenza vaccination is recommended (see Table 61-2).

Drug Interactions and Contraindications

Drug Interactions

Few SSZ-drug interactions are known. SSZ may impair absorption of digoxin and decrease its bioavailability. Rarely, SSZ can increase the effects of oral hypoglycemics and the anticoagulant effects of warfarin. Broad-spectrum antibiotics may alter gut flora and decrease the bioavailability of sulfapyridine and 5-ASA through reduced cleavage of the azo bond.

Contraindications

Patients with hypersensitivity to any component of SSZ, or with a sulfonamide or salicylate allergy, should not be prescribed SSZ. Caution should be used in patients with porphyria or gastrointestinal or genitourinary obstruction. SSZ should not be used in thrombocytopenia, severe liver disease, and active viral hepatitis (see Table 61-2).

ANTIMALARIALS

KEY POINTS

Hydroxychloroquine (HCQ) is a well-tolerated DMARD that is commonly used in combination therapy regimens for RA.

HCQ is more commonly used than chloroquine.

HCQ has a very long half-life, attributed to its affinity for melanin-containing cells in the skin.

Doses of HCQ should not exceed 6.5 mg/kg in chronic therapy to minimize the risk of retinal toxicity.

Although routine laboratory monitoring is not required ophthalmologic screening is an essential component of toxicity monitoring.

Diabetic patients initiating HCQ should be instructed to follow blood sugars closely because of the hypoglycemic effects of the drug.

HCQ is considered safe in pregnancy; it is recommended that most pregnant patients with SLE remain on the drug to improve pregnancy outcomes.

The aminoquinolones, including quinine, were first derived from the bark of the Peruvian cinchona tree, and were originally used to treat malaria. To reduce toxicity, the 4-aminoquinolines, chloroquine (CQ), and HCQ were developed. CQ and HCQ are the most common antimalarials prescribed, although quinacrine is used occasionally.

Chemical Structure

HCQ and CQ are very similar in their chemical structure, differing only by the substitution of a hydroxyethyl group for an ethyl group on the tertiary amino nitrogen of the side chain of CQ. Quinacrine includes the CQ structure, although it is not a 4-aminoquinolone derivative (Figure 61-7).

Actions of Hydroxychloroquine

Antimalarial agents have both immunomodulatory and anti-inflammatory properties, although their precise mechanism of action in rheumatic disease is unknown. Because HCQ and CQ are weak bases, they can pass through cytoplasmic membranes into cytoplasmic vesicles and accumulate, thereby increasing the vesicle pH from around 4.0 to 6.0 and interfering with acid-dependent subcellular functions. This increased pH has several postulated immunoregulatory effects, including stabilization of lysosomal membranes, attenuation of antigen processing and presentation, and inhibition of cell-mediated cytotoxicity.^{213,214} Macrophages and monocytes require precise pH concentrations for protein digestion and antigen processing, which is altered with an increased pH.²¹⁵ Furthermore, receptor assembly is disrupted, including the major histocompatibility complex (MHC) class II molecules, because a higher pH in the endoplasmic reticulum stabilizes the MHC protein with invariant chains and prevents their displacement by low-affinity autoantigens. This, combined with decreased membrane receptor recycling, leads to downregulation of antigen presentation.^{213,215,216} Furthermore, antimalarial treatment has been shown to decrease circulating immune complexes.²¹⁷

Antimalarials also have inhibitory effects on proinflammatory cytokines. CQ inhibits IL-1 and IFN- γ production by monocytes and T cells.²¹⁸ CQ also inhibits macrophage TNF mRNA transcription and endotoxin-induced secretion of TNF, IL-1, and IL-6.²¹⁹ Studies of HCQ have yielded conflicting results in terms of the ability to inhibit TNF, but

Figure 61-7 Chemical structures of antimalarial drugs used to treat rheumatic disease and the basic structure of 4-aminoquinolones. *R* represents the side chain.

HCQ has been shown to block IL-1, IL-6, and IFN- γ production by monocytes.^{220,221}

Apoptosis or cell death plays an important role in regulation of the immune system, and defects in apoptosis may allow for longevity and persistence of autoreactive lymphocyte clones and perpetuation of autoimmunity. Both CQ and HCQ have been shown to upregulate apoptosis and may downregulate autoimmunity by elimination of autoreactive lymphocytes.²¹⁴ Furthermore, antimalarials have been shown to inhibit the proliferative response of human lymphocytes and natural killer cell activity.^{222,223}

Anti-inflammatory properties of the antimalarials include effects on the arachidonic acid cascade caused by downregulation of phospholipases A₂ and C, which contribute to the production of proinflammatory prostaglandins and lipid peroxidation.²²⁴⁻²²⁶ Lipid peroxidation is thought to play a role in apoptosis, particularly in response to ultraviolet (UV)A and UVB irradiation.²²⁷ Antimalarial agents also have antioxidant properties and may protect against tissue damage from free radicals.²²⁸

Antimalarials have several other beneficial effects relevant to rheumatic disease that warrant further discussion. First, they are photoprotective, and this is likely the result of locally induced anti-inflammatory effects.²¹⁴ Second, both HCQ and CQ inhibit platelet adhesion and aggregation, leading to an antithrombotic effect.^{229,230} Third, HCQ

and CQ favorably alter the lipid profile, with reductions in total cholesterol, triglycerides, very low-density lipoproteins (VLDLs), and low-density lipoproteins (LDLs), particularly in patients on concomitant corticosteroid therapy.^{214,231} Finally, HCQ and CQ have been reported to decrease plasma glucose levels through inhibition of insulin degradation in the Golgi apparatus.^{214,232}

Pharmacology

Absorption and Bioavailability

HCQ and CQ are administered orally and are rapidly and completely absorbed, with the peak plasma concentration for both occurring within 8 hours.²³³ Considerable variability in blood concentrations has been reported among patients treated with the same dose, but higher plasma levels do not correlate with a better therapeutic response.²¹⁴

Distribution and Half-Life

Antimalarials accrue in different concentrations in various tissue compartments. Relatively small concentrations, similar to those seen in the plasma, are contained in fat, bone, tendon, and brain. Increased concentrations are seen in the kidney, bone marrow, spleen, lungs, adrenal glands, and liver. The highest concentration occurs in melanin-containing cells, such as those in the skin and the retina.²³⁴ In fact, the skin can serve as a long-term reservoir whereby the drug can exert its effect, or toxicity, even after it has been stopped.²¹⁴ The half-life of HCQ and CQ is 40 to 50 days, and plasma levels will increase gradually and equilibrate after 3 to 4 months.²³⁵

Elimination

Most of the absorbed drug is excreted in the urine unchanged, but some is metabolized to a desethyl derivative. The remainder is excreted in the feces.²³⁶

Indications

Rheumatoid Arthritis. The efficacy of antimalarial agents in rheumatoid arthritis has been seen in their ability to control signs and symptoms of the disease²³⁷⁻²³⁹; however, they have not been shown to retard bone erosions.²⁴⁰ In a meta-analysis of antimalarials, HCQ was found to be less toxic but also less effective than CQ.²⁴¹ In comparison with other DMARDs, symptomatic efficacy is equal to or slightly less than that of other agents, and they have the slowest onset of action.²⁴² Antimalarial agents are particularly suited for use in early, mild rheumatoid arthritis and in combination therapy.

Systemic Lupus Erythematosus. Although antimalarials are not appropriate as monotherapy for severe manifestations of SLE, they are used frequently to control constitutional symptoms, arthritis, fever, fatigue, and rash. The most convincing data supporting the efficacy of antimalarials in SLE come from studies in which the medication was discontinued in successfully treated patients. In one double-blind, placebo-controlled drug discontinuation study of 47 SLE patients in remission on HCQ, the risk of disease flare was increased by a factor of 2.5 in the placebo group.²⁴³

Antimalarials are particularly suited to treat SLE because of their photoprotective effects, and they are especially useful in dermatologic manifestations of SLE.

Discoid Lupus. Antimalarials are effective in discoid lesions, with remission or major improvement reported in 60% to 90% of treated patients.²²³ When HCQ or CQ treatment alone is unsuccessful, the addition of quinacrine may be helpful, but long-term use may be limited by the development of yellowish skin pigmentation.²⁴⁴

Antiphospholipid Antibody Syndrome. HCQ use has been associated with a decreased incidence of thrombosis in patients with antiphospholipid (aPL) antibodies.²⁴⁵ HCQ has also been shown to diminish thrombus size and time in mice injected with aPL antibodies, and to reverse aPL antibody-mediated platelet activation.^{246,247} Although clinical trials are needed to further establish efficacy, it is reasonable to consider the use of HCQ in patients with antiphospholipid antibody syndrome, especially if they are unable to tolerate high levels of anticoagulation, or if they develop thrombosis despite oral anticoagulation.²⁴⁸

Sjögren's Syndrome. HCQ has been shown to improve local eye and mouth symptoms, arthralgia, and myalgia in a prospective open-label study of patients with Sjögren's syndrome.²⁴⁹ In addition to causing the immunomodulatory and anti-inflammatory effects discussed earlier, HCQ may inhibit glandular cholinesterase activity and enhance salivary gland secretion.²⁵⁰

Miscellaneous. Antimalarials have been reported to be efficacious in small and uncontrolled trials for the treatment of palindromic rheumatism,²⁵¹ childhood systemic lupus erythematosus,²⁵² childhood dermatomyositis,²⁵³ eosinophilic fasciitis,²⁵⁴ and erosive osteoarthritis.²⁵⁵ In a controlled trial of 17 patients, the arthritis of calcium pyrophosphate crystal deposition disease improved more in the HCQ than in the placebo group.²⁵⁶

Dosing

HCQ comes in 200-mg tablets, CQ is available in 250-mg and 500-mg tablets, and quinacrine is available from compounding pharmacies. To prevent ocular toxicity, HCQ should be maintained at a dose of 6.5 mg/kg or less for body weight or ideal body weight, whichever is less, and the dose of CQ should be 3 mg/kg or less.²⁵⁷ In practice, doses of HCQ rarely exceed 400 mg daily, in divided doses, and doses of CQ rarely exceed 250 to 500 mg, dosed daily.

Geriatric Patients (See Table 61-1)

No specific pharmacokinetic studies have explored the use of antimalarials in the elderly; thus dosing recommendations are the same as for the general population.¹⁰⁴ Elderly patients should be screened at baseline for pre-existing ocular disease.

Pediatric Patients (See Table 61-1)

HCQ is used at a dose of 3 to 5 mg/kg/day, typically to a maximum of 400 mg/day. To achieve this dosing in younger children and use the 200-mg tablets, the drug can be dosed every other day. Alternatively, HCQ can be compounded in a 25 mg/mL suspension. It is generally recommended that

ophthalmologic screening occur every 6 months; however, some suggest that screening every 12 months is sufficient.

Toxicity

Ophthalmologic

Early eye symptoms can include defects in accommodation or conversion or blurred vision, which resolves. Retinal toxicity is the most feared side effect, although it is rarely seen if proper dosage and monitoring protocols are followed. Fewer than 20 cases have been reported in the literature in more than 1,000,000 patients prescribed the drug, and in a recent review of six cases of retinal toxicity, all arose as the result of dosing above published guidelines.^{257,258} CQ has a higher risk of retinal toxicity than HCQ.²⁵⁹ Risk factors for retinopathy include high dosage, longer duration of use (>5 years), renal or liver disease, and advancing age (>60 years old). HCQ or CQ retinopathy is described as bilateral bull's eye maculopathy, with retinal pigment epithelial (RPE) cell depigmentation in the central macula and sparing of a small foveal island. Testing of the paracentral visual field can usually show toxicity before RPE changes are visible. When advanced, visual loss may be irreversible and may continue despite cessation of the drug because of its long half-life in the retina; so early detection is essential. CQ and HCQ can also cause corneal deposits, which can be associated with halos around lights and are benign and reversible.

Dermatologic

Rash is a common side effect leading to discontinuation of therapy. HCQ may also cause photosensitivity, alopecia, and depigmentation of hair.²⁴¹

Neuromuscular

Common neuromuscular symptoms include headache, insomnia, nightmares, and irritability, which are mild and reversible with lowering of the daily dose. Tinnitus and deafness can occur. Neuromyotoxicity has been reported and presents as proximal weakness of insidious onset with a normal creatine phosphokinase (CPK), which may be associated with peripheral neuropathy and cardiac myotoxicity. Muscle biopsy shows curvilinear bodies and muscle fiber atrophy with vacuolar changes.²⁶⁰

Cardiovascular

Rarely, conduction disturbances and cardiomyopathy have been reported.²⁶¹

Gastrointestinal

Anorexia, nausea, vomiting, diarrhea, and abdominal cramping have been reported.²⁴¹

Metabolic

HCQ can reduce blood glucose levels and hemoglobin A_{1C}, so diabetic patients need to be cautioned to watch their blood sugars closely with initiation of HCQ and may need adjustments in their diabetic medications.²⁶²

Fertility, Pregnancy, and Lactation

No reports have described adverse effects on fertility. HCQ and CQ are considered FDA Pregnancy Category C.¹²³ Because of the long half-life of HCQ, discontinuation of the drug at the time of pregnancy does not avoid fetal exposure. HCQ does cross the placenta, but there have been no reports of adverse outcomes or teratogenic effects in women who continue HCQ during pregnancy.¹²³ CQ also crosses the placenta and binds more tightly in tissue than HCQ; fetal anomalies in women who took CQ during pregnancy have been reported.²⁶³ Quinacrine should not be used in pregnancy because it is mutagenic. Current recommendations are that HCQ may be continued throughout pregnancy, particularly in SLE, where discontinuation could precipitate a flare, which would be dangerous to both mother and baby.¹⁶⁴ HCQ is also found in low concentration in breast milk, but the American Academy of Pediatrics classifies it as compatible with breastfeeding¹²³ (see Table 61-1).

Toxicity Monitoring

The ACR recommends baseline screening with CBC, liver transaminases, and creatinine. Subsequently, no routine laboratory monitoring is recommended.¹²⁴ In 2002, the American Academy of Ophthalmology (AAO) released an information statement on screening recommendations for CQ and HCQ retinopathy.²⁵⁷ Revised guidelines were published in 2011. With new data showing the risk of retinal toxicity increasing toward 1% after 5 to 7 years of use, or a cumulative dose of 1000 g of HCQ, a baseline examination is advised to rule out maculopathy, which may be a contraindication to usage. Subsequently, annual eye examinations should commence at 5 years or sooner depending on other risk factors.^{263a} At a minimum, this should include a dilated eye examination, visual field testing with Humphrey 10-2 fields, and screening for color blindness in male patients. In addition, newer objective tests should be employed that are more sensitive than visual fields (multifocal electroretinogram [mfERG], spectral domain optical coherence tomography [SD-OCT], and fundus autofluorescence [FAf]). Despite these recommendations, many rheumatologists would favor annual screening or, at a minimum, screening every 2 years. Vaccination with a yearly influenza vaccine is recommended (see Table 61-2).

Drug Interactions and Contraindications

Drug Interactions

HCQ should be used with caution in diabetic patients on hypoglycemic agents. HCQ has been shown to increase digoxin levels. CQ may increase cyclosporine levels and reduce MTX levels. CQ can interfere with cytochrome P450 enzymes and should be used with caution when combined with other agents metabolized by this pathway.

Contraindications

Hypersensitivity to or previous retinal or visual field changes attributable to 4-aminoquinoline agents and severe liver disease due to viral hepatitis are contraindications to further use (see Table 61-2).

COMBINATION DMARD THERAPY IN RHEUMATOID ARTHRITIS

KEY POINTS

Monotherapy with MTX infrequently induces remission in RA.

Combinations of DMARDs have been shown to have superior efficacy without increased toxicity.

MTX is the cornerstone of combination therapy.

Current research is focused on the best strategies for introduction, timing, and patient selection for combination therapy.

In the early 1990s, the use of combinations of DMARDs to treat RA was rare; now this strategy is employed by essentially all rheumatologists to treat many of their patients.²⁶⁴ Currently, the timing and make-up of combinations selected to treat RA is one of the most important decisions that clinicians face.

Monotherapy with MTX is considered by most as the initial treatment of choice for early RA. Four major studies have demonstrated the superiority of combinations of DMARDs over monotherapy in head-to-head comparisons.^{66,265-267} Trials with multiple conventional DMARDs and biologics have shown them to be more effective than placebo when added to the baseline MTX in patients who have active disease despite MTX therapy. With very few exceptions, successful combination trials have included MTX, and it remains the cornerstone of combination therapy.

History of Combination DMARD Therapy

Early combination DMARD studies were initiated in the late 1970s. The combination of cyclophosphamide, azathioprine, and HCQ produced substantial responses in a small group of patients; however, an unacceptably high number of malignancies were reported.²⁶⁸ Thus, early enthusiasm for combination therapy was limited. During the 1980s, inadequate dosing, the use of DMARDs with marginal efficacy, and problematic trial design contributed to the less-than-exciting results reported with combination therapy. In 1994, the first trial to convincingly show superior efficacy without increased toxicity of combination DMARD therapy in a head-to-head comparison with monotherapy was reported,²⁶⁹ and multiple trials showing the success of combination therapy have ensued.

Early Rheumatoid Arthritis

In the late 1990s, three pivotal trials showed the success of combination DMARD therapy in early RA. Researchers in the Netherlands reported success with a step-down approach in the COBRA (Combinatietherapie Bij Reumatoïde Artritis) trial.²⁶⁵ In this trial, patients with early disease were randomized to two groups: the combination of prednisolone, MTX, and SSZ was compared with SSZ alone. Prednisolone was started at 60 mg/day, rapidly tapered, and discontinued by week 28. MTX was given until

week 40. The dose of SSZ was the same in the two groups. At 28 weeks, the combination group was significantly better than the SSZ-alone group. As prednisolone and MTX were tapered, clinical responses became similar in the two groups; however, significant benefits in certain parameters were noted in the combination group.²⁷⁰ It is important to note that combination therapy was not more toxic. Subsequent data confirm that the radiographic benefits conferred by COBRA in the initial trial continue for at least 5 years.²⁷⁰

The second important early RA study is the Finland Rheumatoid Arthritis (Fin-RA) trial.²⁶⁷ In this open trial, patients were randomized to receive combination DMARD therapy (MTX, SSZ, HCQ, and low-dose prednisolone) or monotherapy with SSZ with optional prednisolone. The major end point of this trial was remission at 2 years. Significantly, patients who received combination therapy achieved more frequent remissions. A follow-up of this trial at 5 years demonstrated that patients treated initially with the combination were less likely to have evidence of C1-C2 subluxation on cervical spine radiographs.²⁷¹

In a third trial from Turkey, patients with early RA were randomized to single DMARD therapy (MTX, SSZ, or HCQ), two-drug therapy (MTX and SSZ or MTX and HCQ), or three-drug therapy (MTX, SSZ, and HCQ), with remission at 2 years as the major outcome.²⁶⁶ For all end points measured, two drugs were shown to be statistically superior to monotherapy, and three drugs were statistically superior to the two-drug regimens.

The TEAR (Treatment of Early Aggressive RA) trial is the first randomized head-to-head trial in early RA comparing initial combination therapy with MTX, SSZ, and HCQ or MTX and etanercept with initial MTX monotherapy with step-up to combination therapy at 6 months for patients with a Disease Activity Score (DAS) 28 of 3.2 or greater. Results show that initial combination therapy is superior to MTX monotherapy at 6 months, but at 2 years, no differences occur between any of the combination groups, regardless of initial or step-up to combination therapy.²⁷²

In sum, combination therapy, whether step-up or initial therapy, has been shown in multiple trials to be superior to MTX alone in early rheumatoid arthritis. Predictors of who may respond to MTX monotherapy alone and who needs early combination therapy are still lacking.

Patients with Active Disease Despite Methotrexate

Combination DMARD therapy was first studied in groups of patients with active disease despite MTX therapy, or suboptimal MTX responders. The first study to show the advantage of combination therapy with MTX and another DMARD compared with continued therapy with MTX alone in this group of patients was the cyclosporine-MTX trial²⁷³ (Figure 61-8). Therapy with the combination of MTX, SSZ, and HCQ, so-called triple therapy, has been shown to be well tolerated^{66,266,267,274} and more effective than MTX monotherapy^{66,266,272} or SSZ monotherapy,²⁶⁷ and, in an open trial of patients with early disease, more effective than the double combination of MTX and SSZ or MTX and HCQ.²⁶⁶

Figure 61-8 Summary data taken from seven different clinical trials of therapies in patients with active disease despite methotrexate therapy. HCQ, hydroxychloroquine; MTX, methotrexate; SSZ, sulfasalazine.

In 1996, a 2-year, randomized, double-blind, parallel study of 102 established RA patients was done to compare triple-drug therapy (MTX, SSZ, and HCQ) versus double therapy (HCQ and SSZ) versus monotherapy with MTX.⁶⁶ Significantly more patients receiving triple-drug therapy achieved a modified Paulus 50% response,²⁷⁵ compared with those given double therapy. Triple therapy was well tolerated, and numerically fewer withdrawals occurred in the combination group compared with the other two groups. This therapy has been shown to be durable, with 62% of patients remaining on triple therapy for 5 years continuing to maintain a 50% efficacy response.²⁷⁶

In follow-up, a 2-year, double-blind trial on patients with moderately advanced disease was done in 2002, in which the triple combination was compared with two double combinations (MTX plus SSZ and MTX plus HCQ) in a head-to-head comparison.²⁷⁴ Patients were stratified for previous MTX use, and previous users had to have active disease despite receiving 17.5 mg/wk. The triple-therapy group and both double-therapy groups tolerated their treatments well, with only 8% withdrawing for toxicities, which were mostly minor. Triple therapy was shown to be superior to either of the double combinations.

A double-blind, placebo-controlled trial (see Figure 61-8) compared the addition of leflunomide or placebo to baseline MTX in suboptimal MTX responders.²⁷⁷ Leflunomide or placebo was added to MTX. The combination group was statistically superior to the MTX-placebo group in terms of the American College of Rheumatology 20 set (ACR20) criteria for clinical response. The combination was reasonably well tolerated, but side effects including diarrhea, nausea, and dizziness were increased in the combination arm. Elevated ALT levels (>1.2 times normal) occurred more frequently in patients on combination therapy than in those on MTX alone, with increases leading

to withdrawal in 2.3% of patients who received the combination.

In one arm of the previously discussed TEAR trial, combination triple therapy or MTX and etanercept was added for MTX nonresponders. Both groups responded, and eventually no differences were seen in the DAS28 for the step-up group compared with initial combination therapy patients.²⁷²

Corticosteroids in DMARD Combinations

Corticosteroids have not traditionally been considered DMARDs. However, they clearly fulfill all of the criteria for DMARDs, including retarding radiographic progression.²⁷⁸ Few clinicians who care for patients with RA dispute their efficacy. Indeed, they have been used as baseline therapy for well over half of the patients included in the combination trials discussed previously.

Prednisolone undoubtedly was a critical component for the success of the COBRA protocol²⁶⁵ and may have played a role in the success of the combination group in the Fin-RA trial.²⁶⁷ Kirwan and colleagues' report of the ability of prednisolone to significantly retard radiographic progression of RA compared with placebo is testament to the efficacy of steroids when used in combination with other DMARDs.^{278,279} Corticosteroids clearly deserve further formal investigation as a component of combination therapy. The COBRA trial and the Kirwan data have raised another interesting question: Should/could short courses of high-dose steroids be used as a form of induction therapy?²⁸⁰

Biologic Agents in DMARD Combinations

Biologic agents that block TNF (etanercept, infliximab, adalimumab, and golimumab) and IL-1 (anakinra) have
